Keywords: *Agro-morphology, diversity, growth types, fruit yield, Tomato*

INTRODUCTION

Tomato is an important component of the daily diet in Nigeria which is either consumed fresh or in processed form as tomato paste. The demand for tomato in Nigeria is very high and supply is hardly adequate due to low yield caused by inadequate improved cultivars, poor production and management system, pests and diseases among others. The huge demand for tomato is a pointer to the need for breeding programs in order to enhance production efficiency, yield and quality of tomato fruits (Ibitoye *et al.,* 2020). Therefore, the evaluation of tomato germplasm is of great importance for crop agronomic and genetic enhancement in the current and future time (Ramzan *et al.,* 2014). Diversity in plant genetic resources (PGR) provides opportunity for plant breeders to develop new and improved cultivars with desirable characteristics (Govindaraj *et al.,* 2015). Marefatzadeh-Khameneh *et al*, (2021) studied genetic variability in 589 tomato accessions and advocated that germplasm could be used to develop improved genotypes. The lack of genetic variability and unavailability of high-yielding cultivars has been reported to be among the main reasons for low seed production; hence, it is imperative to increase genetic variability to develop high-yielding tomato cultivars by evaluating available germplasm (Brake *et al.,* 2021; Kulus, 2022).

Morphological description and classification is a traditional approach used to quantify genetic differences, and is often used for genetic diversity analysis (Khadivi-Khub *et al.,* 2008; Terzopoulos and Bebeli, 2008; Nikoumanesh *et al.,* 2011). Musa *et al,* (2023) concluded in their study that the application of morphological techniques could be considered to provide suitable parameters for studying the evolution of the genetic divergence among tomato lines. Reports from authors above clearly indicate that genetic diversity is necessary to develop high-yielding genotypes. Also, the evaluation of improved cultivars or breeding lines along side with local materials may enhance selection and hybridization for improved yield and quality as required by Nigerian tomato farmers. Beside breeding, tomato yield can also be enhanced by adopting improved management techniques and good agronomic practices if researchers/farmers understand the agro-morphological traits of available cultivars. The objectives of this study was to evaluate agro-morphological variations among elite and local tomato cultivars for further breeding and use by farmers.

MATERIALS AND METHODS

The study was carried out at the vegetable research field of the National Horticultural Research Institute (NIHORT), Ibadan, Oyo state, Southwestern Nigeria. Twenty tomato accessions comprising of eleven elite lines (obtained from the World Vegetable Centre, Taiwan), three improved commercial varieties (Roma VF, UC 82B and Early spring) and six breeding and local lines (obtained from the Seed Technology Unit, NIHORT) were used for the study. The seeds were raised in the nursery for three weeks and thereafter transplanted to the field at a spacing of 50cm x 50cm. Plot size for each accession was 2m x 2.5m translating to 30 plants per plot. The study was conducted in randomized complete block design with three replications. Hoe weeding, fertilizer application and other necessary crop management and field maintenance were carried out as at when required. In order determine the level of variations among the tomato cultivars, plant characterization based on descriptors for tomato (IPGRI, 1996) was used. Data were also collected on days to 50% flowering and fruiting, fruit set (%) and fruit yield. Quantitative data collected were subjected to analysis of variance and significant means were separated using least significant difference at 5% level of probability.

RESULTS

The result of the plant characterization (Table 1.) based on descriptors for tomato (IPGRI, 1996) revealed high variations based on physico-morphological characters. Three plant growth types were observed among the 20 genotypes of tomato. Semi-determinate/determinate growth type dominated the tomato accessions (78.26 %) while other accessions had indeterminate growth types (21.74 %). Stem internode length ranged from sparse to long with highest number of accessions exhibiting long internode length (43.48 %). The foliage density ranged from sparse to dense with majority of the accessions exhibiting intermediate foliage density (65.22 %) while 8.70 % of the accessions displayed sparse density and others (26.09 %).

A close look at the accessions showed that, 16 exhibited many numbers of leaves under first inflorescence while 3 exhibited few number of leaves. The leaf attitude ranged from semi-erect to drooping with majority of the accessions (39.13 %) displaying drooping leaf attitude. Standard leaf type dominated the accessions with 82.61 % while 17.39 % of the accessions exhibited other leaf types. However, none of the accessions exhibited dwarf and potato leaf type. Style position ranged from inserted to highly exerted (Table 1). The blossom end fruit shape for 81.82% of the accessions is flat, 13.64 % is indented and for 4.55 % is pointed while the blossom end scar 77.27 % of the accessions is closed as the remaining 22.77 % is open.

In table 2, days to 50% flowering ranged between 26 (in Ibadan L17) and 40 (in AVTO 1219). Ibadan L17 was also observed to have reached 50% fruiting earliest with 34 days. There were six other accessions with early fruiting (cherry 19, AVTO 1920, Alausa 20, AVTO 1429, AVTO 1906 and Ker-Ojik). The accessions with late flowering and fruiting were five. The result further revealed that five accessions had more than 70% fruit set (Ker-Ojik 22, Alausa 20, Cherry 19, Kercash 23 and K/Wali). Intermediate fruit set was observed in 10 accessions while two accessions had slightly less than 50% (Ibadan L17 and AVTO 1219) fruit set. The remaining three accessions had between 50 and 59% fruit set (Table 2). A cursory look at table 3 revealed that number of fruits ranged significantly from 261 in Cherry

19 to 14 in AVTO 1424. Number of fruit was also found to be high in Ker-ojik 22 with 147 fruits. With regards to fruit yield per plant, fruit weight per plot and total marketable weight (t/ha), the highest number of fruit recorded in Cherry 19 did not ultimately translate to highest fruit yield per plant, fruit weight per plot and total marketable weight (t/ha), as Ker-ojik gave the highest with 3.54 kg, 73.8kg and 141.7 tons respectively. Other accessions with high fruit yield per plant, fruit weight per plot and total marketable weight (t/ha) were Ibadan L17 and Kercash 23. Cherry 19, Alausa 20, AVTO 1429, AVTO 1920 were in the third categories in terms of yield. Accessions with low fruit yield per plant, fruit weight per plot and total marketable weight (t/ha) were UC 82B, Roma VF, AVTO 1909. The data on non- marketable yield revealed that three accessions (Early spr 18, Ibadan L17, K/Wali) top the list with more than 4/tha. There were seven accessions with very low non-marketable fruits of 1.0 - 1.5 tons/ha. The results also showed that Ibadan L17 though with high yield also had high very high non-marketable yield (4.38 t/ha).

DISCUSSION

Morphological parameters, molecular techniques, and genotype origins are essential tools that can be used to improve cultivars (Luo *et al.,* 2010). The results from this study has shown some distinct traits and similarities among the tomato accessions evaluated and their performance in Ibadan which falls in the derived savanna agro-ecological zone. In terms of earliness, Ibadan L17, Cherry 19, Alausa 20, AVTO 1920 AVTO 1429, AVTO 1906 and Ker-Ojik were identified while Ker-ojik, Ibadan L17 and Kercash exhibited high yield potential. Gumasta *et al,* (2023) evaluated 17 tomato ecotypes and identified maximum morphological parameters for the tomato ecotype VNR(THT)9/2020 and further recommend it as suitable for cultivation in Bhopal region farming community (India). The high non marketable fruit in Ibadan L17 accession among others will require further improvement and major causes will further need to be evaluated. The low non-marketable fruits in AVTO 1706, AVTO 0301, AVTO 1219, AVTO 1906, AVTO 1907, Roma VF and Cherry 19 may be further evaluated for consideration in breeding and use. Further evaluation of these tomato accessions for pests and diseases will be required as this information can aid in making informed decisions regarding tomato selection, breeding including cultivation practices, and crop management strategies for sustainable production.

ACKNOWLEDGEMENT

This study was supported by the grant from Korea-Africa Food and Agriculture Cooperative Initiative (KAFACI: Project Number: KAH20200110), Rural Development Administration of Korea.

ABSTRACT
Cashew apple utilization is very low considering its production capacity of Nigeria. Motorized juice extractor, manual mechanical juice extractor and hand-squeezed juice method were studied to compare their effects on selected performance parameters and quality parameters of cashew apple juice. Mechanical juice extractors showed low extraction efficiency and rate with high extraction losses. But mechanical manual extractor indicated similar quality values with manual-hand squeezed method. The motorized juice extractor requires improvement to produce juice that will meet quality standard. Further study to determine optimal performance conditions of the mechanical extractors may yield better results.

INTRODUCTION

Many fruits provide helpful benefits because of their vitamins and mineral composition including detoxifying properties. Unfortunately, many people find ease access to these fruits difficult due to unavailability in readily forms. Cashew apple is nutritious and very rich in Vitamin C (270 – 300mg/100ml) which is reportedly to be 5 and 10 times that of oranges and pineapples respectively (Ugwu and Okonkwo, 2022).The juice is also possesses therapeutic properties in forms of minerals and antioxidants which are believed to be effective for treating some ailments, such as dysentery, stomach ulcers and gastritis (Diana et al 2021).The high juice content of about 85% of cashew apple (Ogunwolu, 2017 and Olalusi et al, 2020) and its by-products such as pulp which can be processed into other useful products makes it very suitable to proffer solution to active hunger.For instance, high fibre content of 15 - 18% of cashew apple (Dagadkhair *et al*. (2018) can be used as dietary fibre in foods or as base in animal feeds. Africa Cashew Alliance estimated that 18% of the population's Vitamin C requirement will be met by processing just 15% of cashew apple. Farmers' income would also increase averagely by 15.5%with about 0.9 billion US dollar increase in G.P.D of producing countries in Africa. Akinnibiosun and Oyetayo (2018) stated that World market for cashew will remain strong in the future due to the considerable potentials of high valued by-products. Ibirogba (2019) claimed cashew has higher production capacity and lower production cost than those of its competitors like cocoa which make it well suitable for economic recovery and industrialization. Utililzation of cashew apples is an additional income since it is an integral part of the fruit that produces the nut, which is a significant economic commodity, and does not require extra investment or labour input for production. Extraction of the juice through appropriate indigenous sustainable technologies will encourage storability and prolong the shelf life.

Nigeria is one of the world leading cashew producers, producing about 960,000 M.T. nuts per annum (Ibirogba, 2019). It was reported as second major crop after cocoa (Akinnibiosun and Oyetayo, 2018 and Ibirogba, 2019). Cashew apple is an integral part of the fruit which consists of the nut and the apple reported to be about 9 – 12 times the weight of the nut (Dimoso, 2020); every one tonne of cashew nut produces estimated 8 – 10 tonnes of cashew apples claimed Dagadkhair *et al*. (2018). The use of cashew apples and by-products is an opportunity to diversify farm activities and economy. Surprisingly, cashew apples are currently left to rot on the farms despite its enormous potentials and opportunities for commercial exploitation. Only 6 – 10% of the Nigeria's cashew apple production is utilized (Ugwu and Okonkwo, 2022 and Olalusi *et al*. 2020). According to Africa Cashew Alliance, cashew apple usage across all raw cashew nut (RCN) producing countries in Africa is insignificant as no country is processing greater than 1% of its total cashew apple production. The very small percentage utilized is mostly consumed raw by squeezing fresh through the mouth. The overall juice market in Sub-Saharan Africa was also growing at an average of 12-15% as further stated. Cashew apples are seasonal and highly perishable, due to high sugar content, resulting in low utilization. The astringency of the apples due to high content of tannins causing harsh taste has also been identified as a major factor for low consumption of the juice. This must be appropriately removed to a reasonable level through blanching/boiling before extraction (Bolarinwa et al. 2020). The most practicable way of prolonging the storage life of fruits is the extraction of the juice content according to Martins *et al*. (2018). They added that fruit juices can be stored for months or years depending on preservation and packaging methods. Development of juice extractors using local materials at minimal cost with required effectiveness and efficiency will improve availability of juices at affordable prices, increase their consumption and reduce postharvest losses Zhenchen *et al*. (2020) had studied the performance of some selected mechanical apple juicers and stated considerable differences in terms of extraction factors and juice quality. Information on such study for cashew apple juice extraction is very scarce. Nigeria produces enormous quantity of cashew apples, but very little portion of this production is consumed as raw apples. Proper extraction of juice from these apples through sustainable technologies resulting in quality and acceptable products will promote utilization of nutritious benefits of cashew apples, reduce apple losses and increase farmers' income. It is therefore worthwhile to investigate proper ways of extracting cashew apple juice which will promote consumption of its high Vitamin C and mineral contents, increase farmers' income and apple reduce losses.

Therefore, this study aimed to determine the suitability of mechanical method of extracting juice from cashew apples using machines of different operational principles with a view to encourage improved juice extraction and quality for better consumption and utilization of the juice.

MATERIALS AND METHOD

Materials used for this experiment were a motorized juice extractor, a manual mechanical extractor, muslin cloth, gas cooker, cooking pots, digital stop watch, digital weighing scales, plastic bottles, plastic bowls and fresh cashew apples.

Description of the mechanical juice extractors

The motorized juice extractor comprised of the extraction chamber made of a perforated cylindrical barrel, housing a worm shaft driven by a pulley and belt system. A conical piston is located at one end of a screw shaft which was supported by two ball-bearings. The barrel was lagged by a screen mesh with smaller holes than those of the barrel, meant for juice filtration. A trapezoidal hopper was located at one end on the top of the barrel while two outlets for discharging the juice and the pulp respectively were located below the discharge tray connected to the barrel. The manual juice extractor comprises of the extraction chamber made of a perforated cylindrical barrel, housing a screw conveyor driven by hand through a handle welded to the screw shaft. A conical piston was welded to one end of the screw shaft supported by a ball-bearing. A bevel gear attached to the conveyor shaft was driven by a bigger bevel gear attached to the end of the handle. A trapezoidal hopper was located at one end the barrel. The juice discharge tray positioned below the barrel had two different openings for discharging the juice and the pulp respectively. By comparison, the motorized extractor consisted of a warm shaft while the manual extractor was made of a screw conveyor. A screen was also present in the extraction chamber of the motorized extractor while it was not in the manual. A petrol engine is the power source of the motorized extractor while that of the manual type was by human effort aided by a gear system.

Preparation of Experimental Materials

Cashew apples used for this experiment were plucked directly from trees from the plantation of Cocoa Research Institute of Nigeria, Ibadan headquarters, located within Latitude 70^0 30'N and $30^0$54'E at an altitude of 200m above sea level. The apples were processed immediately as recommended by Ogunwolu(2017) that they should be juiced within 3 hours of harvesting. The apples were first sorted to select those that were of quality, their nuts were removed as they were washed. Blanching of the apples was carried out in boiling water for 10 minutes as reported by Bolarinwa *et al*. (2020).

Experimental Procedure

About 1.5 kg each cashew apple picked randomly from the blanched bulk was measured through the digital weighing scale (model ZE 11 and 1g sensitivity). Each of the apple samples was fed into each of the motorized juice extractor (MJE) and manual juice extractor (MME) respectively and replicated 3 times. Juice of 3 samples of the same weight as used for the mechanical extractors was squeezed by hand using muslin cloth (MHE). Quantity of the juice extracted juice left and extracted manually by hands (measured by weighing balance KERRO BL5002 of sensitivity 0.01) and the pulp were weighed and recorded. The time taken for extracting juice from each sample was measured using stopwatch (model Timeless, and accuracy 0.001secs). Pasteurization is an intrinsic part of fruit juice processing to ensure microbial safety and to inactivate enzymes such as polyphenol oxidase (PPO), and peroxidase (POD) that could lead to undesirable sensory and nutritive changes (Petruzzi et al., 2017) to ensure the juice is fit for consumption. Extracted juice samples were also pasteurized in plastic bottles before storage. Physical parameters, which include pH, specific gravity, degrees brix, colour and sedimentation test was checked on the extracted cashew juice after 24 hours of extraction. The hand expelled; fresh unpasteurized cashew juice was used as control. Also, heavy metals present were quantified in the cashew juice.

Performance Evaluation and Data analysis

The data obtained from the experiment was processed manually using scientific digital CASIO calculator and analyzed through SAS software (version 9.1)to determine the following parameters according to Adeleke *et al*. (2017) and Unuigbe *et al*. (2018):

Extraction efficiency, EF (%): $\frac{Je}{Je+Jhs} \; x \; 100$

1

Extraction losses, EL (%): $\frac{[(Fs-(Je+Rw)]}{Fs} \; x \; 100$

2

Extraction rate/capacity, ER(kg/hr): $\frac{Je}{T}$

3

Where:

Je – Juice extracted by machine, Jhs - Juice hand squeezed, Rw – Residue waste, Fs – Feed sample, T – Time taken for juice extraction

RESULTS AND DISCUSSION

Effects of extraction methods on machine extraction parameters

It was indicated that different methods of cashew apple juice extraction had effects on the extraction parameters (Table 1). The mean extraction efficiency of the manually operated extractor was lower but comparable to that of motorized type. Both mechanical extractors had very low efficiency compared to the hand squeezing method. This might be due to machine design, including the operating factors such as feed rate and machine speed. However, low extraction efficiency had been reported by Adeleke *et al*. (2017). Motorized extractor had the lowest extraction rate compared to considerably equal values for the other two methods. This might be caused by juice losses or poor extraction due to speed of the motorized extractor. Zhenchen *et al*. (2020) had reported low juice extraction rate of 29.4 – 47.0kg/hr for manual apple juicer while Martins *et al*. (2018) stated 38.9 kg/hr for a motorized citrus extractor. The extraction losses of motorized and manual extractors were much higher than the hand squeezed method. This could be due to poor extraction or machine leakages. This can have a negative implication on the purpose for designing the machine as it determines the economic value. High extraction losses of a motorized cashew apple extractor reported by Adeleke *et al*. (2017) were attributed to possible high speed and poor machine assembling. Optimizing the extractor performance operation of the two juice mechanical extractors may improve results.

Table 1: Effects extraction methods on juice extraction parameters

Methods/Treatments	Dependent Variable	Mean	Std Dev	Minimum	Maximum

MHE- Manual-hand expelled, MME- Manual mechanical extractor, MJE- Motorized juice extractor

Table 2 indicated that the efficiency of both mechanical extractors, which were not significantly different, was different from that of the hand squeezing. Both the extraction rate and extraction losses were not different significantly for the three juice extraction methods investigated.

Table 2: Comparison of significance of the extraction methods

Methods/Treatments	EF	ER	EL
MJE	56.543b	19.923a	52.420a
MME	54.547b	26.580a	42.510a
MHE	100.000a	25.050a	8.937a

*Means with the same letter along the column are not significantly different at 0.05 sig. level

Effects of extraction methods on juice quality parameters

The pH of cashew juice obtained from manual hand expelled (MHE), manual mechanical extractor (MME) and motorized juice extractor (MJE) methods were 3.8 and 3.9(Table 3). The control, unpasteurized hand expelled juice, had a pH value of 3.7 bearing close similarity with others. From these results, all the cashew juice obtained were acidic, and falls within the allowed limits by the Standard Organization of Nigeria, that is; 1.4-4.0 (SON, 1997). It was therefore evident that material makeup of the equipment does not significantly alter the acidity of the juice. The specific gravity of all the juices ranged between 1.046 - 1.062, although observed specific gravity for fresh unpasteurized sample was lower, an indication that less solute were extracted. Specific gravity as observed with these different methods showed more pulps were dissolved into the body of the juice as noted with manual mechanical extractor and motorized juice extractor. Brix indicated that the dissolved solids that are being measured consist entirely of sucrose. The soluble sugars; as observed in fresh unpasteurized cashew juice, was 9.7 compared with those found in pasteurized samples. Increased brix level in cashew juices obtained from the MHE, MME and MJE, was a response to pasteurization activity involved. Total sugars (Brix), found in MHE and MME agreed with the Standard Organization of Nigeria's prescription except the sample obtained from MJE which exceeded stipulated limit (7-14%). Colour as measured by spectrophotometric method, with fresh unpasteurized cashew juice showed marked difference when compared with cashew juice expelled using the listed methods. Juice extracted by MJE showed lowest colour (absorbance-1.114) as a result of shorter extraction time. Heat treatment effect on the sugar content, caramelisation, imparts colour build-up on all the juice. The sediment content (measured by centrifugation method in gramme) in cashew juice extracted increased with extraction methods as fresh unpasteurized juice had least (1.02) sediment while it increased in MHE, MME and MJE (10.63- 13.48).

Table 3: Physical parameters of cashew juice extracted using different methods

Parameters	MHE	MME	MJE	Control
pH	3.8	3.9	3.9	3.7
SG	1.046	1.048	1.062	1.038
Brix (%)	11.3	12.1	15.3	9.7
Colour 380/420 (nm)	1.309	1.696	1.114	0.989
Sediment (g)	10.63	12.50	13.48	1.02

SG- specific gravity.

Table 4 showed the trace metal in the extracted cashew juice obtained from the different methods. Chromium, Cadmium and Lead were absent (nil) in the extract. Copper in cashew juice extracted using motorized juice extractor was higher (2.763 mg/l) than in manual-hand expelled sample and manual mechanical extractor. No significant difference in amount of copper in cashew juice obtained from both MHE and MME. Obtained results falls within the maximum allowable limit of 5 mg/l, specified by FAO/WHO (SON, 1997). Zinc, another metal of importance was present in the cashew juice extract. Cashew juice produced using manual hand expeller and manual mechanical extractor compares abundantly with permissible limit of SON. Therefore, it is considerably safe to employ these methods in cashew juice processing. On the other hand, excess zinc (13.04 mg/l) was quantified in cashew juice expelled using motorized juice extractor, MJE. The iron content (21.33 mg/l) in the cashew juice extracted with motorized juice extractor was beyond stipulated norm (15 mg/l). This was an indication of iron deposits from the material make up in the equipment. A likelihood of wear in component parts of the extractor was suspected. Iron contents of cashew juice obtained from manual-hand expeller (2.42 mg/l) and manual mechanical extractor (10.41 mg/l) were within limits. Arsenic was not determined.

Table 4: Trace metals in cashew juice extracted using different methods

Heavy metals (mg/l)	MHE	MME	MJE
Copper	0.397±0.08	0.423±0.03	2.763±0.10
Iron	2.420±0.11	10.410±0.18	21.330±0.22
Chromium	Nil	Nil	Nil
Cadmium	Nil	Nil	Nil
Zinc	1.249±0.07	1.703±0.15	13.035±0.21
Lead	Nil	Nil	Nil
Arsenic	ND	ND	ND

ND- Not determined.

CONCLUSION

Juice extracted by mechanical methods indicated low values for selected machine performance parameters. Manual-hand expeller and manual mechanical extractor produced better juice quality. The motorized juice extractor needs to be improved to meet required quality standard. Further study of the performance of the mechanical extractors that may give better results is recommended.

ABSTRACT
Optimal crop production in sandy soils is limited by their poor water and nutrient holding capacities. The immediate and residual effects of Tithonia diversifolia (TD) biochar types on soil properties and fresh biomass wight (FBW) of Amaranthus hybridus in chemical fertilizer treated soil under leaching condition was evaluated. The experiment was a factorial combination of three tithonia biochar types: sole TD tagged (B1), TD co-pyrolyzed with poultry manure (PM) (tagged B2) and TD co-pyrolyzed with PM and bone meal (tagged B3) and two chemical fertilizers: NPK 15:15:15 (tagged NPK) and urea. Checks that received neither biochar (tagged NB) and chemical fertilizer (NCF) were compared. Each biochar type was applied at 5 t/ha (equivalent to 0.75 g/300 g soil) and each chemical fertilizer applied at 120 kg N/ha (equivalent to 0.12 and 0.04 g NPK and urea per 300 g soil respectively). The treatments were arranged in completely randomized design with three replications. The test crop A. hybridus was nurtured for 4 weeks each in amended soil during two consecutive cropping. Results indicated that biochar pretreatment significantly increased FBW of A. hybridus with higher performance during the residual cropping with higher positive residual effects in chemical fertilizer soils pretreated with B1 and B3. The FBW increased by 276.4, 59.8, 130.2 and 199.1% in sole biochar, biochar pretreated NPK, biochar pretreated urea and sole chemical fertilizer soils respectively during the residual compared to immediate cropping. The study highlighted the importance of biochar characteristics and nutrient composition in influencing its effectiveness in enhancing soil chemical characteristics and crop yield.
Keywords*: Tithonia biochar, Residual cropping, NPK 15:15:15, Urea, Amaranthus hybridus, Calcareous soil, Sandy soil.*

INTRODUCTION
Chemical fertilizers are important recurring farm inputs for efficient crop production (Khan et al. 2022). They have contributed immensely to enhanced crop production in the world. Their continued use among farmers as major soil fertility management tool is linked to their fast nutrient dissolution potential in soil, ease of application, transportation and subside given on it by most African governments. Africa's chemical fertilizer usage is reported to be much lower than in other countries, with an average of less than 25 kg per hectare of farmland. This is significantly lower than countries like China, where usage is around 400 kg per hectare (FAO, 2019). The reality of increasing loss of fertile farmland in Africa especially from farms intensively managed by chemical fertilizers is not in tandem with the low fertilizer usage data in Africa. Poor documentation of farming activities and input usage by local farmers in Africa could be attributed to inability to properly ascertain current chemical fertilizer usage in most African countries.
Indiscriminate sole use of chemical fertilizers especially on light textured soils characterized by low water and nutrient holding capacities is without adverse environmental implications (Zhang et al., 2023; Li et

al., 2023; Fidel et al 2018). For example, manufacturing and field application of nitrogenous fertilizers such as urea, ammonium sulphate and NPK fertilizer variants have been implicated as major drivers for enhanced global greenhouse gas emissions, soil acidification, surface and underground water eutrophication and organic matter depletion in soils (Wu et al., 2023). The need therefore to develop resilient system in light textured soils yearly receiving increasing chemical fertilizer treatments is essential for future food and environmental security in Africa. One of the approaches that has been well reported is the use of biochar (Hou et al., 2023; Wu et al., 2023)

Biochar is a carbon-rich solid product from the thermal decomposition of biomass in the absence of oxygen. Its porous surface, large surface area and well distributed functional groups have made it an efficient soil amendment for improved water and nutrient holding in soil and as a mitigation tool for greenhouse gas emissions from soils (Zhang et al., 2023; Li et al., 2023). Research outputs on effects of co-application of biochar with chemical fertilizers is increasing annually but little of such have been documented for sandy soils in Africa. This work hypothesized that biochar pretreatment in chemical fertilizer treated soil would improve soil characteristics for eventual increased biomass yield of crop over two consecutive cropping. The work therefore assessed immediate and residual effects of one-time application of biochar produced from *Tithonia diversifolia* modified with or without poultry manure and bone meal on biomass yield of *Amaranthus hybridus* in sandy soil managed by common chemical fertilizers during two consecutive cropping.

MATERIALS AND METHODS

Soil sampling and routine analysis

The soil studied was from the fallowed section of the Greenhouse site of the department of Horticulture, Cape Peninsula University of Technology, Cape Town, South Africa (33°55'45.53" S, 18°38'31.16" E). The soil is formed under Mediterranean climate characterized by cold and wet winter and hot and dry summer. Top soil of 0-15 cm depth was sampled using hand trowel. The soil was air dried and sieved with 2 mm mesh sieve followed by laboratory routine analysis. The soil pH was extracted by 1.0 M KCl and distilled water in soil to extractant ratio of 1:2 read using pH meter earlier standardized in buffer 4, 7 and 9 solutions. The electrical conductivity of the soil extracted by distilled water above was read using an EC meter. Soil available phosphorus (P) was extracted by Olsen procedure using 0.5 M sodium bicarbonate solution. Exchangeable cations and soil cation exchange capacity (CEC) were extracted by 0.2 M ammonium acetate at pH 7. For the CEC determination, the soil was pre-leached with 0.2 M K_2SO_4 followed by total NH_4 extraction with 1 N KCl and colorimetric determination on the SEAL Auto Analyzer 3 with 15 mm flow cell and 520 nm filter. The particle size was by chemical dispersion of the soil in sodium hexametaphosphate followed by sedimentation at 20℃ using ASTM E100 (152H-TP) hydrometer. The total carbon (TC) was by combustion method in the TOC analyzer (elementar Model) at 950 ℃. Initial acidification of the soil sample with 10% HCl acid to liberate the carbonate components in the soil which represents the total inorganic carbon (TIC) in the soil was carried out. The combustion of the resultant oven dried acidified samples at 950 ℃ gave the total organic carbon (TOC). The difference between TC and TOC was thereafter taken as the total inorganic carbon (TIC) of the soil.

Biochar production and their nutrient composition determination.

The shoot biomass of *Tithonia diversifolia* (TD) was used as the basal feedstock for the production of the biochar studied. Sole TD biochar was by pyrolysis of 30 g of TD in the laboratory furnace at 400 ℃. Pyrolysis of 15 g of TD mixed with 15 g of air-dried poultry manure (PM) at 500 ℃ gave the TD+PM biochar while further spiking with 10 g each of TD, PM and bone meal at 400 ℃ all at 20 mins residence time gave the TD+PM+BM biochar. The C and N in the biochar was determined in the C and N elemental analyzer. The energy dispersive spectroscopy (EDX spectroscopy) was used for the determination of P, Ca, Mg and K in the biochar samples after been sputtered with gold. The ash content was estimated from combustion of biochar samples in the furnace at 550℃.

Treatments and experimental set up

The experiment was a factorial combination of three biochar types: sole TD (tagged B1), TD+PM (tagged B2) and TD+PM+BM (tagged B3) and two chemical fertilizer types: NPK 15:15:15 (tagged NPK) and urea. Each biochar was applied into 300 g soil in a leaching column at 5 t/ha (equivalent to 0.75 g/300 g soil). Each of the chemical fertilizer was applied at 120 kg N/ha (equivalent to 0.12 and 0.04 g NPK and urea per 300 g soil respectively. The treatments with no biochar (NB) and no chemical fertilizer (NCF) were included for comparison. This gave twelve treatments laid in completely randomized design with three replications.

During the immediate cropping, each biochar type was applied two weeks before the chemical fertilizer application for proper equilibration after been moistened to field capacity. Two weeks old *A. hybridus* vegetable seedlings of equal height were transplanted at one plant per column into each biochar amended soil with or without appropriate chemical fertilizers. The seedlings were thereafter nurtured for four weeks. All the aforementioned were repeated during the residual cropping without fresh application of each of the biochar types.

Data collection and analysis

The harvested vegetable from each column was weighed on the measuring scale after all the adhering soils unto the roots were washed under running water and wiped with soft towel. The soil sampled from each treated soil after harvesting during the residual trial was subjected to pH, electrical conductivity, TOC and TIC determination following procedures earlier described. The two-way analysis of variance was utilized for the statistical analysis of the data collected and means were separated by LSD at $p<0.05$. Simple linear regression was conducted to assess the contributions of selected soil parameters from the chemical fertilizer soil pretreated with biochar to fresh biomass yield of *A. hybridus*.

RESULTS

Characteristics of the soil studied

The soil is a light textured calcareous soil characterized by very high concentration of exchangeable Ca with alkaline pH of 8.01. The soil has moderate phosphorus, TOC and TIC contents. The soil was dominantly sandy (Table 1).

Nutrient characteristics of the biochar tested

The biochar made from sole *T. diversifolia* (sole TD) has the lowest ash content and highest total carbon and nitrogen contents resulting in biochar with highest C/N ratio. Fortification of *T. diversifolia* with poultry manure with or without bone meal as found with TD+PM and TD+PM+BM respectively, modified the nutrient composition of the resultant biochar types. These modified biochar types had higher ash contents, lower carbon and nitrogen contents to achieve lower C/N ratios compared to what was obtained from sole TD biochar.

Immediate and residual effects of tithonia biochar pretreatments on fresh biomass weight of *A. hybridus* in soil treated with common chemical fertilizers

Chemical fertilizer (CF) types significantly influenced fresh biomass weight (FBW) of *A. hybridus* during the immediate cropping. (Fig. 1). The NPK based treatments gave highest FBW. Biochar pretreatment prior chemical fertilizer application significantly improved FBW in both NPK and urea-based treatments relative to sole chemical fertilizer application. For instance, pretreating soil with B2 and B3 prior to NPK fertilizer application significantly increased FBW by 122 and 39.6% respectively compared to sole NPK application. All the three BC types significantly enhanced FBW in urea-based fertilizer treatments. Soil pretreatment with B1, B2 and B3 prior to urea application increased FBW by 48.9, 45.6 and 73.4 % respectively compared to sole urea treatment.

B1= biochar from sole *T. diversifolia* at 400°C, B2= biochar from *T. diversifolia* plus poultry manure at 500°C and B3= biochar from *T. diversifolia* plus poultry manure and bone meal at 400°C.

With reference to sole CF types, FBW produced was in the order of NPK > urea > NCF while the order B1 > B2 > B3 > NB was followed for FBW produced for sole biochar treatments during the immediate cropping. Biochar application prior to NPK and urea usage consistently increased FBW by mean values of 50.8 and 56.0% respectively compared to their individual sole chemical fertilizer application across all the biochar types. The NPK fertilizer was most responsive to B2 for increased FBW production while urea had superior response with B3. During the residual cropping, the biochar types, chemical fertilizer types and their interaction did not significantly affect the FBW of *A. hybridus*. Although, the FBW produced here were drastically higher than what were achieved from their corresponding treatments during the immediate cropping. Soil that received neither biochar nor chemical fertilizer was responsible for the least FBW produced which was similar to the observation from the immediate cropping. The NPK-based treatments consistently produced higher FBW. The potential of the biochar types to enhance FBW of *A. hybridus* seems to shift during the residual trial. Only B1 and B3 pretreatment improved FBW over sole chemical fertilizer application in NPK and urea -based treatments respectively.

During residual cropping, FBW in earlier sole B1, B2 and B3 treated soil increased by 285.4, 290 and 242.3% respectively compared to immediate cropping. The FBW of Amaranthus in NPK treated soil pretreated by B1 and B3 increased by 224 and 60.2% respectively while FBW in B2 pretreated soil reduced by 11.1% during the residual cropping. Sole NPK treated soil also increased FBW by 138.7% during the residual cropping compared to the immediate cropping.

Immediate and residual effects of tithonia biochar pretreatments on fresh biomass weight of *A. hybridus* in soil treated with common chemical fertilizers

Chemical fertilizer (CF) types significantly influenced fresh biomass weight (FBW) of *A. hybridus* during the immediate cropping. (Fig. 1). The NPK based treatments gave highest FBW. Biochar pretreatment prior chemical fertilizer application significantly improved FBW in both NPK and urea-based treatments relative to sole chemical fertilizer application. For instance, pretreating soil with B2 and B3 prior to NPK fertilizer application significantly increased FBW by 122 and 39.6% respectively compared to sole NPK application. All the three BC types significantly enhanced FBW in urea-based fertilizer treatments. Soil pretreatment with B1, B2 and B3 prior to urea application increased FBW by 48.9, 45.6 and 73.4 % respectively compared to sole urea treatment.

Effects of biochar pretreatments on electrical conductivity (EC) and pH of soil treated with common chemical fertilizers after the residual cropping

Soil EC after residual cropping was significantly affected by biochar type, chemical fertilizer type and their interaction (Table 3). All the treatments significantly increased EC contents of the soil at the end of the trial. The final soil EC was in the order of NPK > urea > NCF and B3 > NB > B1 > B2 for the sole chemical fertilizer and biochar treatments respectively. Pretreating NPK treated soil with B2 and urea treated soil with B3 significantly increased soil EC above other biochar types. Consistent least EC values were recorded from urea -based treatments with values below what were observed from soil with neither chemical fertilizer nor biochar pretreatment and sole biochar treatments. (indicating least labile nutrient concentrations in the urea -based treatments at the end of the trial).

Soil pH at the end of the residual cropping was significantly affected by biochar and chemical fertilizer types (Table 3). The pH values were higher in sole biochar treated soils followed by urea and NPK based treatments (indicating increasing soil acidification potential of NPK > urea > sole BC treatments). The B1 was responsible for highest pH values in both the NPK and urea-based treatments representing 1.2 and 1.1

% increases compared to sole NPK and urea treated soils respectively. The NPK-based treatment consistently produced the least pH values across all treatment factors.

Table 3: Effects of biochar pretreatments on electrical conductivity (EC) and pH of soil treated with NPK 15:15:15 and urea fertilizers after the residual cropping

	Soil EC (µS/cm)				Soil pH

The total inorganic carbon (TIC) and total organic carbon (TOC) were significantly affected by biochar type, chemical fertilizer type and their interaction (Table 4). The TIC and TOC values observed in all the treatments were below the initial 2.63 and 5.02% respectively prior to commencement of the work. The NCF treatments that received no chemical fertilizers were generally highest in TIC and TOC followed by urea and NPK based treatments (indicating intense TIC decomposition in the NPK fertilizers). Sole B3 and sole NPK treated soils had highest (2.85%) and lowest (1.93%) TIC contents respectively. Biochar pretreatment of urea treated soil with B1, B2 and B3 increased TIC by 23.3, 8.7 and 5% respectively while only B2 and B3 pretreatments increased TIC by 11.9 and 15 % respectively in NPK treated soil relative to their individual sole chemical fertilizers. The NCF treatments again produced higher TOC followed by NPK and urea-based treatments. The TOC content was interestingly highest (1.78%) in unamended soil which received neither biochar nor chemical fertilizer and least value (1.10%) from urea soil pretreated by B2. The B1 and B3 were responsible for higher TOC and TIC contents respectively in the soil studied.

Contributions of selected soil parameters to fresh biomass weight or *A. hybridus* in chemical fertilizer treated soil pretreated with different tithonia biochar types.

The contributions of the soil parameters considered to the FBW of *A. hybridus* is in the order of TIC > EC > pH > TOC (Fig. 2). This represented about 55, 53, 24 and 0.7% variations accounted for changes in FBW of A. hybridus by TIC, EC, pH and TOC of the soil studied respectively. All the selected soil parameters except soil EC had negative relationship with FBW of the test crop. Although, all the contributions of the soil parameters considered to the FBW were not significantly influenced.

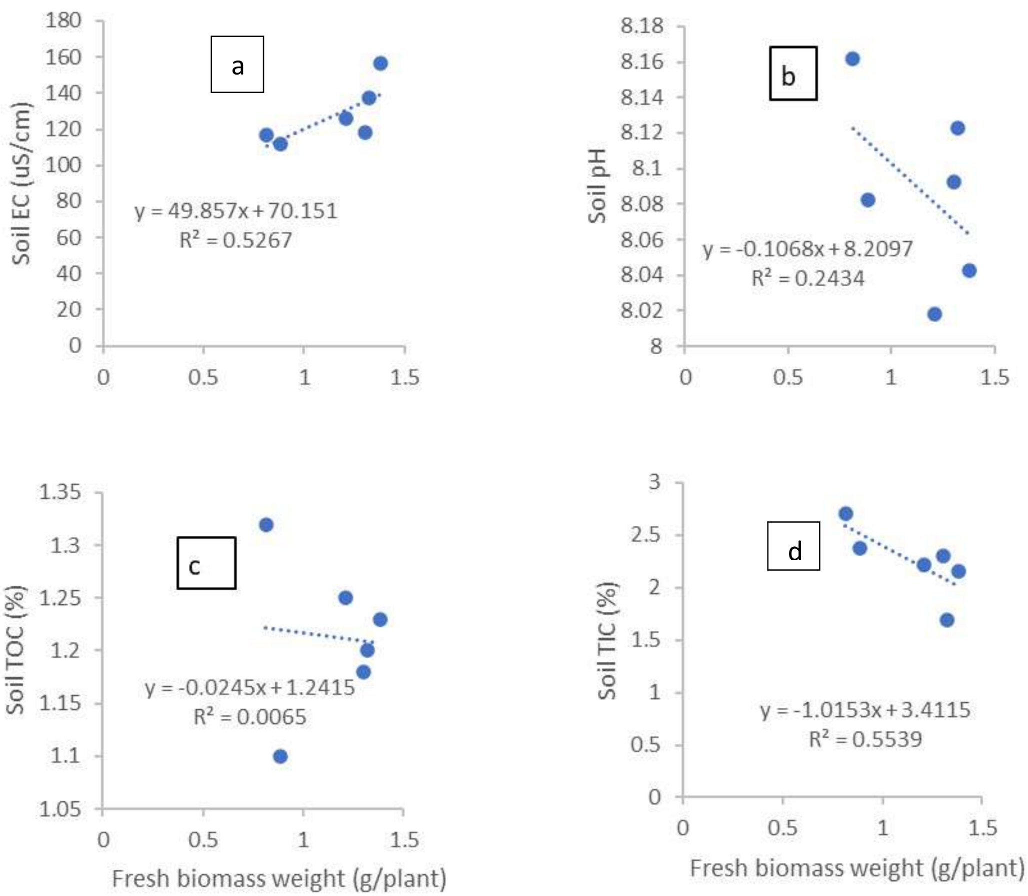

Fig. 2: Contributions of selected soil EC (a), pH (b), TOC (c) and TIC (d) to fresh biomass weight of *A. hybridus* in chemical fertilizer treated soil pretreated with different tithonia biochar types.

DISCUSSION

The sandy calcareous soils are widely spread in the arid and coastal regions of the world (Taalab et al., 2019; Aboukila et al., 2016). Their use for crop production is limited by their poor water and nutrient holding capacity (Alghamdi et al., 2023). This condition makes these soils susceptible to faster nutrient leaching especially under increasing rainfall influxes leading to reduced fertilizer use efficiency and environmental pollution (Khan et al., 2022). This present work hypothesized that the pretreatment of sandy soil before chemical fertilizer application with biochar produced from *T. diversifolia* and modified with or without poultry manure and bone meal, will improve soil characteristics and lead to increased fresh biomass yield for *A. hybridus* over two consecutive cropping seasons.

Biochar pretreatment significantly increased FBW of A. hybridus during both cropping trials. The work underscores the positive residual potentials of the biochar tested as indicated by their multiple fold increases in the FBW of A. hybridus during the residual cropping compared to the immediate cropping. Similar increased biomass yield of Amaranthus was reported by Islam et al., 2020; Punnoose and Anitha, 2017) following biochar application. The ability of B1 and B3 to support higher biomass yield during the immediate cropping compared to BI could be linked to their lower carbon contents and C/N ratios and higher ash contents. These characteristics supported increased nutrient mineralization rate compared to the sole TD biochar. The sole TD biochar (BI) however required longer period for its optimal nutrient dissolution as indicated by its higher proportionate contribution to biomass production of the test crop especially under the sole biochar and co-application with NPK. Nutrient composition including ash, carbon and macronutrient contents as well as C/N ratios are therefore important parameters to consider for biochar in biochar that will guarantee nutrient availability under immediate or residual application conditions. In this trial, B1 guaranteed higher positive residual effects on soil characteristics and eventual fresh yield of the test crop compared to B2 and B3. However, the higher ash composition of the B3 and B2 contributed to their potentials to enhance TIC over TOC. The BI on the other hand supported higher TOC as a result of its high innate carbon content over B2 and B3. This corroborates the submission of Zhang et al. (2023) and Wang et al. (2022).

The FBW depression observed during the residual cropping in NPK soil pretreated with B2 could be linked to reactions between the high nutrient mineralizing potentials of the B2 and the NPK fertilizer characterized by high nutrient solubility. These innate characteristics of the B2 and NPK fertilizer predispose the soil to higher nutrient losses and dissolved organic carbon during the leaching simulation that was done weekly in each amended soil. This also explained the generally lower TOC and TIC in all the amended soils as well as the untreated soil that received neither biochar nor chemical fertilizers. The weekly leaching process which mimicked rainfall impacts on the soil was sufficient to encourage faster organic and inorganic carbon dissolution in the soils. Although, the impact of the weekly simulation was more severe in chemical fertilizer soils that were not pretreated with biochar. In fact, TOC and TIC where generally significantly higher in absolute control soil compared to sole chemical fertilizer treated soils.

The large surface area and porous nature of biochar have been reported to be instrumental in modifying the soil structure for improved water and nutrient holding capacities (Hou et al., 2023; Wu et al., 2023; Fidel et al., 2018). This eventually leads to reduced nutrient leaching, volatilization and enhanced uptake by plant for improved biomass production (Gu et al., 2022). The generally higher FBW in biochar pretreated soils from the current work rightly affirm this report. The regression model revealed the significant contribution of nutrient mineralization and buffering from the two carbon pools of the soil. This is consistent with the submissions of Khalil et al. (2023). The negative correlation in the TOC and TIC indicated supply of nutrients from this nutrient bank into the soil solution. This effect was confirmed by the generally increases in the electrical conductivity readings from each of the amended soil. The EC has been reported as an indicator of nutrient ion concentration in the soil (). The increasing EC in the soil as a result of nutrient concentration increases during the residual cropping therefore explains the positive relationship between EC and the FBW of A. hybridus.

CONCLUSIONS

The study highlighted the importance of balancing the use of chemical fertilizers with sustainable soil management practices to ensure food and environmental security in Africa. The use of tithonia biochar was evaluated for potential solution to enhance soil quality and crop productivity while mitigating the negative environmental impacts of chemical fertilizers. The study emphasized the importance of considering nutrient composition, including ash, carbon, macronutrient contents, and C/N ratios when selecting biochar as pretreatment for chemical fertilizer treated soils. These parameters play significant role in ensuring nutrient availability under immediate and residual application conditions. The different biochar types (B1, B2 and B3) studied had varying effects on crop yield. Biochar types with lower carbon contents and C/N ratios and higher ash contents (such as B1 and B3) supported higher biomass yield during the immediate cropping compared to BI (sole Tithonia diversifolia biochar) and vice versa.

The study indicated that certain biochar types such as B2 had high nutrient mineralizing potential, and when used in combination with NPK fertilizer, which has high nutrient solubility, could lead to soil conditions that encouraged higher nutrient losses and dissolved organic carbon during leaching simulations. This could result in decreased total organic carbon and total inorganic carbon in the soil. Summarily, the study demonstrated the potential of biochar as a soil amendment to improve the productivity of sandy calcareous soils, especially when used in conjunction with chemical fertilizers. It highlighted the importance of biochar characteristics and nutrient composition in influencing its effectiveness in enhancing crop yield and reducing nutrient leaching.

ABSTRACT
This study was conducted to examine the insecticidal potential of nano-synthesized Petiveria alliacea Leaf and Root applied at three different concentration (5, 10, and 20%) against the observed insects (Riptortus dentipes and Mylabris pustulata) of cowpea at Ladoke Akintola University of Technology, Teaching and Research Farm Ogbomoso during the planting season of cowpea, 2021. Synthetic insecticides (chlorpyrifos) and negative control were included in the treatments for comparison. The experimental land was demarcated and arranged in a Randomized Complete Block Design and each treatment was replicated three times. Data were collected on insects' infestation density, pod damage (%), number of root noodles, and the number of yields (t/ha). Significant means were separated using Duncan Multiple Range test at 5% probability level. All the tested Nano insecticides were effective against the observed insects but none of the tested insecticides was as effective as chlorpyrifos. Also, the effectiveness of Nano. P. alliacea leaf and root depended on the observed insects. Nano P. alliacea root and leaf at 20 % v/v compete effectively with Chlorpyrifos with respect to pod damage meanwhile the plants treated with Nano P. alliacea leaf at 20% v/v had the highest significant yield (0.51 t/ha). However, all the treatments had the same significant effect on the number of root noodles. Therefore, nano-insecticides from P. alliacea leaf and root can be used in the management of field insect pests of cowpea.
Keywords: *Riptortus dentipes, Nano formulations, Petiveria alliacea, Mylabris pustulata Chlorpyrifos, Cowpea*

INTRODUCTION
Cowpea (*Vigna unquiculata* L. walp) belongs to the family Fabaceae (Ibrahim, 2017). This crop was reported to have originated from West and Central Africa, and is a major source of protein in many parts of Africa (Enyiukwu *et al.*, 2018). The major constraint in the cultivation of cowpea is insect pest infestations which cause up to 70% grain yield loss Alao and Adebayo (2011). Among the insect pests of cowpea, post-flowering insects such as *Meglurothrips sjostedti* Tryborn, *Maruca vitrata*, Fabricious *Clavigralla tomentoscollis* and *Riptortus dentipes* (Jackai and Adala, 1997; Alao *et al*., 2011) have been implicated to have caused major economic lost. To protect this crop from pest attack, farmers usually rely on quick pest management options, mainly synthetic chemicals (Alao and Adebayo, 2011). However, the use of synthetic insecticides has several challenges such as development of pesticide resistant pests, and harmful effects on humans and the environment (Shabana *et al.*, 2017). Due to the aforementioned problems, botanical insecticides have been explored and discovered to successfully control insect pests. The importance of botanical pesticides is attributed to their efficacy, biodegradability, varied modes of action, low toxicity as well as availability of source materials (Riyaz *et al.,* 2022).
Extracts of *Petiveria alliacea* have demonstrated acaricidal (Rosado-Aguilar *et al.,* 2010), antinociceptive (Gomes *et al.,* 2005), insecticidal (Akanbi *et al*., 2007), analgesic and antioxidant effects. Nanoparticles can be defined as materials and systems whose structures and components exhibit novel and significantly improved physical, chemical and biological properties, phenomena and processes due to their nano scale

size i.e. in a range of 1-100 mm (Agbaje *et al.,* 2016). There is a tremendous scope for the development of novel bio oriented natural pesticides from a combination of nano particles and plant-based chemicals which is highly environmentally safe, biodegradable and effective. Therefore, this study was conducted to examine the insecticidal potential of nanosynthesized *P. alliacea* leaf and root against *R. dentipes* and *M. pustulata* infestations on cowpea plants.

MATERIALS AND METHODS

Study Site

The study was carried out at Ladoke Akintola University of Technology (LAUTECH) Teaching and Research Farm (longitude 40 301E and latitude 10051N). The region climate could be described as hot humid tropical falls in Southern Guinea Savana Nigeria with a mean temperature of 27ºC and annual rainfall of 1400 mm. It is marked with dry and wet seasons, characterized by a bi-modal rainfall pattern with peaks in July and September.

Experimental Design and Management

The experimental land was ploughed and harrowed once and 24 plots were demarcated and arranged in a Randomized Complete Block Design, and each treatment was replicated three times. The plot dimension was 4 m by 4 m, with a planting distance of 1 m between each plant stand. The total number of plants stand per plot was 25 stands. Cowpea variety (Ife Brown) was planted and three seeds were dropped per planting hole, and thinning was done two weeks after planting to one plant per stand. Weeding was done manually at two weeks interval.

Nano Formulation

P. alliacea roots were chopped into pieces manually. *P. alliacea* roots and leaves were air dried at room temperature for three weeks. Grinding of the leaves and roots were done separately with mortal and pestles. Powdered root and leaves of *P. alliacea* were measured separately with electronic sensitive-scale and they were later taking to the Nano-technology laboratory at the Microbiology Department, LAUTECH, for further processing.

Nano formulation of *P. alliacea* was done following the already established procedures by (Agbaje *et al*., 2018). One gram of *P. alliacea* leaf and root powders were measured out separately which was then dissolved in 100 ml of distilled water, and allowed to stay in water bath at 60^0 C for an hour. The solution was filtered with a filter paper, then centrifuged the filtrate at 4000RPM (Revolutions per minute) for 20 mins. The clear supernatant was used for the synthesis. The supernatant was reacted with 40 ml of 1 mm Silver Nitrate solution, and it was later placed under sunlight for photo-activation. Afterwards, the colour change was observed till a stable colour was obtained.

Treatment Application

Application of the treatments commenced three weeks after planting. Nano-formulated *P. alliacea* root and leaf extracts were applied at three different concentrations (5, 10, and 20% v/v) while synthetic insecticide (Chlorpyrifos) was applied at manufacturer's recommended rate. Untreated plots were included in the treatments for comparison. Each of the extracts was diluted with 1000 ml of water to achieve the same spraying volume. Application was done with hand sprayer of 2 L capacity and this was done early in the morning.

Chlorpyrifos	1 m/ 1 L
Control	-
Nano *Petiveria alliacea* leaf	5 %, 10 %, and 20 % v/v
Nano *Petiveria alliacea* root	5 %, 10 %, and 20 % v/v

Data Collection and Analysis

Data were collected on insects' population density and this was done by visual observation from the two middle plant rows. However, counting of the insects on the field was done a day after the application of the treatments for four consecutive weeks. Data were also collected on the followings; number of damage pods/plot, root noodles, and weight of the grain was taken with the sensitive scale and converted to yield (t/ha), Data collected on insects were transformed using square root transformation while data on percentage were transformed with log transformation before subjecting them to analysis of variance (ANOVA) and means were separated using Duncan Multiple Range Test (DMRT) at 5% probability level using Statistical Analysis Software (SAS), v2.0 (2005).

RESULTS

Table 1 shows the effect of insecticide on yield, pod damages, and number of noodles. At 20 % concentration, Nano *P. alliacea* root and *P. alliacea* leaf competed effectively with Chlorpyrifos, as the nano formulation had the most significant effect on preventing pod-sucking insects. Meanwhile, Nano *P. alliacea* leaf had the highest significant effect on the yield parameters of the tested plants. With respect to number of noodles, no significant difference was detected between the treated plants and untreated plants.

Table 1: Effect of Insecticide on Yield, Pod Damages, and Number of Noodles

Treatment	Rate	% Pod damages	Noodles	Yield (t/ha)
Nano *P. alliacea* root	5	28.67^{d}	3.33^{a}	0.31^{e}
	10	52.00^{bc}	3.33^{a}	0.25^{d}
	20	75.00^{a}	4.00^{a}	0.44^{b}
Nano *P. alliacea* leaf	5	38.33^{cd}	3.33^{a}	0.11^{e}
	10	62.33^{ab}	3.00^{a}	0.37^{c}
	20	81.00^{a}	3.33^{a}	0.51^{a}
Chlorpyrifos	-	71.33^{a}	3.33^{a}	0.37^{bc}
Control	-	43.33^{c}	4.33^{a}	0.09^{e}

Means with the same superscript(s) are not significantly different

Figure 1 demonstrated the efficacy of insecticides on *R. dentipes* infestations on cowpea plant. Nano *P. alliacea* root 20% had the highest insecticidal effect on *R. dentipes* infestations compared to other insecticides. The above mentioned nano formulation performed better than the synthetic insecticides.

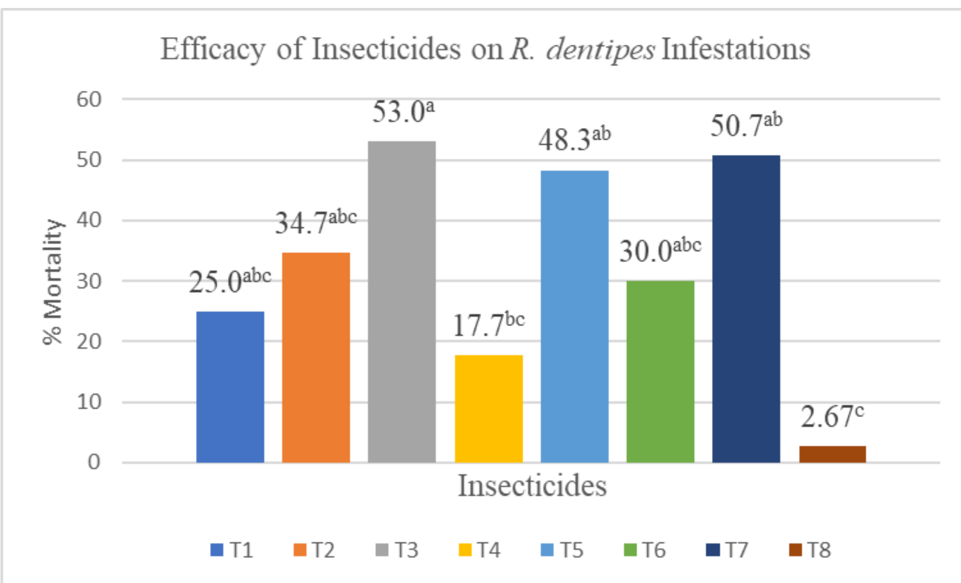

Figure 1: Efficacy of Insecticides on *R. dentipes* Infestation

Key: T1 = Nano *P. alliacea* root 5%; T2 = Nano *P. alliacea* root 10%; T3 = Nano *P. alliacea* root 20%; T4 = Nano *P. alliacea* leaf 5%; T5 = Nano *P. alliacea* leaf 10%; T6 = Nano *P. alliacea* leaf 20%; T7 = Chlorpyrifos; T8 = Control

According to Figure 2, all the tested nano-insecticdes had significant effect on flower beetle infestations. However, both nano *P. alliacea* root and leaf at 20 % concentration, competed effectively with Chlorpyrifos

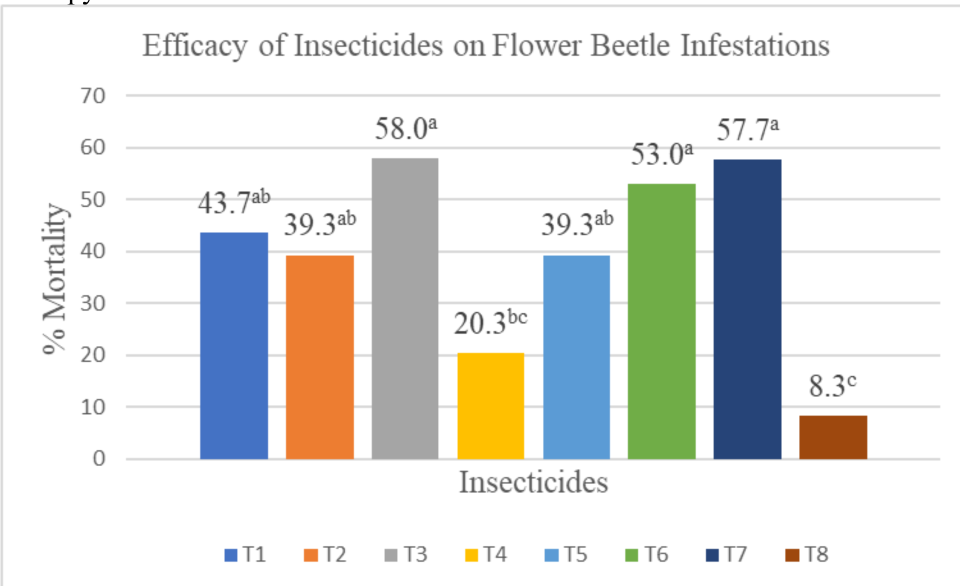

Figure 2: Efficacy of Insecticides on Flower Beetle Infestations

Key: T1 = Nano *P. alliacea* root 5%; T2 = Nano *P. alliacea* root 10%; T3 = Nano *P. alliacea* root 20%; T4 = Nano *P. alliacea* leaf 5%; T5 = Nano *P. alliacea* leaf 10%; T6 = Nano *P. alliacea* leaf 20%; T7 = Chlorpyrifos; T8 = Control

DISCUSSION

Management of field insect pests is necessary in order to have a reasonable yield of crops. However, these have negative effects on humans and the environment, apart from being costly for resource-poor farmers (Kusi *et al.,* 2019). Use of biopesticides is gaining more attention as alternative to synthetic insecticides in the control of field insect pests both in the developed and underdeveloped countries (Akutse *et al*., 2020). Many of these countries are banning the use of synthetic chemicals because of the reported poisonous residual (Ileke and Ogungbite, 2014). In the recent years, nanoparticles have been receiving much attention in the field of agriculture (Guan *et al*., 2008). Rouhani *et al*. (2011) reported that ZnO-TiO2-Ag nanoparticles have insecticidal activity on *Frankliniella occidentalis* Pergande and showed the most mortality effect pertained to 28%ZnO-70%TiO22%Ag (LD50 = 195.27 mg L-1).

All the tested nano insecticides significantly controlled the observed insect pets when compared with the untreated plants which had highest population density of the observed insects. This is in line with Dialoke *et al*., (2017) who reported that the application of all rates of formulated neem seed oil controlled *Riptortus dentipes* infestation. The nano *P. alliacea* insecticide formulated from leaf and root at 20% concentration competed effectively with Chlorpyrifos against flower beetle infestations. This agrees with Alao and Adebayo (2011), who stated that the application of *Tephrosia vogelii* and *P. alliacea* crude extracts at 20% concentration proved to be more effective against the three observed insects – *Maruca vitrata*, *Megalurothrips sjostedti*, and *Riptortus dentipes* when compared with other tested concentrations. However, nano *P. alliacea* root at 20% concentration had higher insecticidal efficacy than Chlorpyrifos when tested against *R. dentipes* infestations, while Nano *P. alliacea* leaf at 10 % concentration had the same insecticidal potential as Chlorpyrifos.

The data suggest that nano *P. alliacea* root had more insecticidal ability than the leaf. This suggests that the root might have had higher insecticidal active chemical compounds than the leaf, this observation is in line with Akintan *et al*., (2021) who reported that *P. alliacea* root possessed higher insecticidal compound than the leaf. Nano *P. alliaceae* root at 20 % concentration had the highest insecticidal potential against *R. dentipes*. This agrees with Alao and Adebayo (2011), who reported that the single application of the *T. vogelii* and *P. alliacea* extracts at 20% concentrations were the most effective against *M. vitrata*, *M. sjostedti*, and *R. dentipes* field insect pests of cowpea. However, during this research study, no dead insects were found on the experimental plot. This indicates that the mode of action of the formulated nano-insecticides can be repellent or anti-feedant which is the nature characteristic of botanical insecticides because they are not true insecticides (Isman, 2008; Dubey *et al*., 2010). The results revealed that cowpea plants treated with nano-formulated *P. alliacea* leaf applied at 20 % concentration had the highest yield. This is in line with Ghidan *et al*., (2020) who reported that Zinc 50 and sulfur 200 nano-particles concentrations significantly increase the plant yield of broad bean.

CONCLUSION

Based on the results of this research, nano insecticides successfully prevented field insects' infestations of cowpea plant. Also, nano-insecticides should be applied at highest concentration in order to have higher yield. Therefore, nano-insecticides can be incorporated into insect pest management program of cowpea especially in the organic farming system. However, further field studies should be conducted on the use of nano insecticides against other field insect pest of crops.

ABSTRACT
Coffee is a perennial beverage crop grown in Nigeria and other countries of the world, serving as a good source of livelihood and income for many. However, insect pests such as coffee leaf miners, Leucoptera spp. (Lepidoptera: Gracillariidae), coffee berry borer, Hypothenemus hampei (Ferrari) (Coleoptera: Curculionidae: Scolytinae), coffee white stem borer, Xylotrechus quadripes (Coleoptera: Cerambycidae); Coffee mealybugs, Coccoidea, (Hemiptera: Pseudococcidae); Antestia bug, Antestiopsis spp (Hemiptera:Pentatomidae) and the coffee green scale, Coccus spp. (Hemiptera: Coccidae) causes significant damage to the crop. Several measures have been adopted by farmers, particularly, the use of synthetic insecticides which have destructive effects on both man and the environment. Globally, some researches have been conducted to check the potency of extracts and essential oils of some botanicals against these pests. The results obtained revealed that the plant samples tested were found effective against the insect pests. Therefore, any of the botanicals evaluated here can be explored as biopesticides against the insect pests. Future research should concentrate on isolation and characterization of active components in these plants samples.
Keywords*: Coffee, Botanicals, Insect pests, Synthetic insecticides*

INTRODUCTION

Coffee is a perennial crop belonging to the family Rubiaceae in the genus *Coffea* which are mostly evergreen trees and shrubs. They are said to have originated from Africa comprising of more than a hundred species. The two main cultivated and commercially utilized species are the *Coffea arabica* L. and *C. canephora* var. *robusta* Pierre ex A. Froehner. (Mendesil, 2019; Waller et al., 2007). The most widely cultivated species globally is *C. Arabica* as it is considered to produce beans of good quality, hence has a higher market value. On the other hand, *C. canephora* is better adapted to warmer and more humid tropical environments than *C. arabica* and able to withstand more adverse conditions. *Coffea arabica* is cultivated on the highlands, while *C. canephora* is grown in the lowlands. More so, *C. canephora* is usually more resistant to coffee pests than C. Arabica (Mendesil, 2019; Rutherford *et al.,* 2006)

Coffee is one of the world's most economically important agricultural produce in many developing countries. It is the main source of income for a good number of people, predominantly the low income farmers in rural areas (Barera, 2017). Coffee is high value low volume cash crop and more profitable than cereal crops as a result of its high demand in International market (Sharma *et al*., 2015). It is been taken as beverage globally due to its health benefits, taste and aroma. Coffee beans and leaves possess some phytochemicals which have both ant-inflammatory effect and antioxidant potency in man (Alli *et al.,* 2021, Eva *et al.,* 2016).

The successful cultivation and production of Coffee is threatened by a host of factors, insect pest attack is significantly top the list. Various insect pests attack different parts of coffee from seedling stage all through to the maturity stage of the plant. It was reported that over 3000 species of insects attacks coffee globally and being a perennial crop, it provides a very conducive environment for these insect pests to thrive (Mendesil, 2019; Waller *et al.,* 2007). However, it is only a few of these insect pests that are significant in the effective production of coffee as they cause a reduction in yield and lower the qualities of coffee bean. The major insect pests of coffee are; coffee leaf miners, *Leucoptera* spp. (Lepidoptera: Gracillariidae), coffee berry borer, *Hypothenemus hampei* (Ferrari) (Coleoptera: Curculionidae: Scolytinae), coffee white stem borer, *Xylotrechus quadripes* (Coleoptera: Cerambycidae); Coffee mealybugs, Coccoidea, (Hemiptera: Pseudococcidae); Antestia bug, *Antestiopsis* spp (Hemiptera:Pentatomidae) and the coffee green scale, *Coccus* spp. (Hemiptera: Coccidae) (Mendesil, 2019; Rutherford *et al.,* 2006). Table 1 below shows the major insect pests of coffee.

The objective of this paper is to evaluate the efficacy of botanicals in the management of the major insect pests of coffee around the world. This was achieved with the aid of published articles by various researchers on coffee and the management of several insect pests.

Management of coffee insect pests with chemical insecticides

Several chemical insecticides such endosulfan which is used against the coffee berry borer, aldrin, lindane among others are being used by coffee stakeholders in managing this crop. Though they've been reported to be effective, they pose a lot of threats to the environment as they are highly poisonous. Also, dependence on synthetic/chemical insecticides is having serious detrimental effect on natural enemies and has resulted in to the development of resistance to various organophosphates. The indiscriminate use of chemical insecticides equally makes coffee bean not acceptable in the international market due to high chemical residues (Merhi *et al*., 2022; Vega *et al*., 2006; Noel and Fontana, 2018).

Botanical insecticide which has been documented to be non- persistence in the environment, selective towards beneficial and non-target organisms, low toxicity to humans and mostly affordable has been found as a good alternative to the use of chemical insecticides (Chengala *et al.,* 2017). Various plant extracts, essential oils and isolated compounds have been discovered to have insecticidal activity against many stored product pests (Alabi *et al*., 2023; Noudegbessi *et al*., 2021; Aikpokpodion *et al*., 2013). Table 2 below summarizes studies that have been conducted in the laboratory on some plant species (with insecticidal activities) from different families used in the management of the insect pests of coffee. All the plant species listed have been reported to cause high mortality and/or repellence against the tested organisms (Mendesil, 2019; Barrera *et al*., 2017; Zorzetti *et al*., 2012).

Table 1: Major insect pests of coffee

S/N	Common name	Insect species	Order and family	Host coffee plant	References

Relationship between insecticidal properties of botanicals and their phytochemical compositions

Plant synthesizes a host of phytochemicals such as flavonoids, tannins, phenol, cardiac glycosides, saponins, alkaloids and others. These secondary metabolites have been documented to exhibit various biological activities, insecticidal activities inclusive. From Table 3 above, all the botanical species used against the insect pests of coffee have the major phytochemicals such as saponins, alkaloids, flavonoids, and phenols. These are known to have activity against pathogens and therefore aid the insecticidal activities of botanicals. The mode of action of these phytochemicals seems to be their ability to tamper with the physiology and behavior of the insect pest which consequently result into death (Maazoun *et al*., 2019; Pavela *et al.*, 2017).

Flavonoids have been found to have insecticidal potency and report has it that these compounds can regulate the feeding and oviposition behavior of insects (Simmonds, 2003). In a study conducted by Salunke *et al.,* (2005), flavonoids were found to be toxic to adults and eggs of *Callosobruchus chinensis* (L.) at a dose dependent rate. Maazoun *et al*. (2019) tested quercetin dehydrate, rutin hydrate and naringin and discovered that all the three flavonoids were active as aphicides against the woolly apple aphid. More so, alkaloids have been reported to play a pivotal role in mortality and antifeedant deterrent against several insect pests. Khani *et al. (2011)* tested the extracts of *Piper nigrum* which has as much as 99% alkaloids against *Sitophilus oryzae* and the results showed that mortality rates of adults increased with increasing concentration of the extract. Yang Ge *et al.* (2015) reported that alkaloids derived from C*ynanchum mongolicum* are potential insect inhibitors as they appear to disrupt insect hormone balances. They were equally found to have contact toxicity against the aphid *Lipaphis erysimi.* tannins are toxins Tannins are toxic substances that significantly minimize the growth and survival of many herbivores and also serve as feeding repellent to a great number of insects leading to their eventual death (Sarma *et al*., 2019).

CONCLUSION

The successful production of the economically important beverage plant, coffee is threatened by the insect pests infestation.The use of synthetic insecticides has been discouraged due to their adverse effects on humans and the environment. This brought about the discovery of the botanical pesticides which serves as a great alternative. It is very germane to preserve coffee tree from the infestation by its various pests using any of the botanicals listed in this review as they have been proven to have insecticidal potentials against the insect pests. Further works have to be done on identification and characterization of the active ingredients present in these botanicals.

EFFECTS OF BLANCHING AND PACKAGING MATERIALS ON SOME CHEMICAL COMPOSITION OF OKRA (*Abelmoschus esculentus L. Moench*) STORED IN EVAPORATIVE COOLANT STRUCTURE

Babatola L.A. and Makinde V.T.
Department of Crop and Horticultural Sciences, University of Ibadan, Ibadan

ABSTRACT
Okra (Abelmoschus esculentus L. Moench) is a highly perishable vegetable prone to quality and nutritional losses during storage. The study carried out in the laboratory of the Department of Crop and Horticultural Sciences, Faculty of Agriculture, University of Ibadan investigated the impact of blanching and different packaging materials on some chemical compositions of stored okra fruits in Evaporative Coolant Structure (ECS). Blanched and unblanched okra fruits packaged in sealed and perforated plastic were stored, and the crude protein, ascorbic acid, and mucilage contents were measured at 4-day intervals. Data were subjected to analysis of variance. Results showed that unblanched okra and okra packaged in sealed plastic had better preservation of mucilage content, ascorbic acid levels, and crude protein compared to blanched okra and okra packaged in perforated plastic. The chemical composition of unblanched okra was preserved for 8 days but declined at 12 and 16 days after storage (DAS).
Keywords: *Evaporating Coolant Structure (ECS), Days After Storage (DAS)*

INTRODUCTION

Okra [*Abelmoschus esculentus (L.) Moench*] is an economically important vegetable crop grown in tropical, sub-tropical, and warm temperate parts of the world (Camcius, *et al*., 1998; Kang *et al*., 2010). Okra is an annual dicotyledonous herb that belongs to the Malvaceae or mallow family and is a relative of cotton (*Gossypium hirsutum L.*). It is grown for its leaves, fruits, seeds, floral parts, and stems. Okra is prominent because of its high nutritive and medicinal value, ease of cultivation, wide adaptability, and pleasant flavor (Lamont, 1999). However, the post-harvest management of okra stands out as one of the most important parts of okra farming. Due to their high-water content (90%) and strong metabolism, which is characterized by a fast respiratory rate, vegetables become extremely perishable after harvest (Mota *et al*., 2010). Okra has a limited shelf life and may deteriorate quickly if not maintained properly, despite its value. Blanching is a process that involves briefly subjecting vegetables to heat (often boiling water or steam), followed by quick cooling. This can help to remove dirt, lower the microbial load, and inactivate enzymes that could otherwise lead to spoiling (Kaur and Singh, 2015). Okra can benefit from proper packing by being shielded from physical harm, exposed to less air and moisture, and protected from microbial contamination (Müller *et al*., 2018).

The effectiveness of the preservation process depends on the appropriate use of packaging materials. The quality of the food product can be impacted by the diverse features of the packaging materials (such as plastic films, paper, and metal cans). In light of the unique requirements of the food product, it is crucial to choose an appropriate packaging material (Oliveira *et al*., 2017). In addition to blanching and packaging, storage conditions can also be used to extend the shelf life of okra. These conditions involve storing the vegetables in a cool, dark, and dry environment with minimal air circulation. This can help slow down the metabolic processes that lead to spoilage and maintain the quality of the vegetables for a longer period (Sharma *et al*., 2017).

The Food Safety and Inspection Service (FSIS) of the United States Department of Agriculture (USDA) recommends keeping blanched vegetables, including okra, in a sealed container in the refrigerator at a temperature of 4°C or lower (USDA FSIS, n.d.). Okra cannot be stored in a refrigerator, which is the conventional method of storing it after blanching in Nigeria because the power supply is frequently interrupted. There is a need to investigate alternative, non-electric methods of storage such as evaporative coolant structures. Packaging materials play an important role in extending shelf life and maintaining the chemical composition of okra. The study was set up to evaluate the effects of blanching and packaging materials on the ascorbic acids, protein, and mucilage content of okra stored in ECS.

MATERIALS AND METHODS

Experimental site and source of sample

The experiment was conducted between November 2, 2022, and November 18, 2022, in the laboratory of the Department of Crop and Horticultural Sciences at the University of Ibadan. Okra fruits (Kirikou F1 variety) were sourced from a vegetable farm in Alabata, Moniya, Ibadan, Oyo state.

Preparation of okra for storage

The okra fruits were sorted and cleaned to remove any debris or unwanted materials. The okra fruits were then divided into two portions. The first portion was blanched with water at the temperature of 100°C for 5 minutes and cooled in ice water for 5 minutes. The second portion was left unblanched. Each portion was then divided into 250 g batches and packaged into different packaging materials (sealed plastic and perforated plastic) before storage.

Experimental design and data collection

The 2 x 2 factorial experiment was laid out in a completely randomized design with four treatments replicated 3 times. The ascorbic acid, crude protein, and mucilage content of the okra fruits were determined at four-day intervals throughout the storage period using procedures outlined by AOAC (Association of Official Analytical Chemists) methods (2005). Data collected were subjected to analysis of variance (ANOVA) using GenStat software. Means were separated using the Least Significance Difference (LSD) at a 5% probability level.

RESULT

The Mean Temperature (^{0}C) and Relative Humidity (%) of The Storage Conditions

Evaporative coolant structure (ECS), had a relative humidity of 89%, and the mean temperature in the morning, afternoon, and evening was 20.5°C, 22.0°C, and 20.4°C, respectively. On the other hand, the open shelf storage had a relative humidity of 75%, and the mean temperature in the morning, afternoon, and evening was 27.8°C, 32.2°C, and 28.1°C, respectively as shown in (table 1).

Effect of Blanching on Crude Protein, Mucilage Content, and Ascorbic Acid of Okra

The effect of blanching on some chemical composition of okra fruits was investigated as shown in (table 2). Results showed that there was a significant difference between blanched and unblanched okra fruits from 4 to 8 days after storage (DAS) except at 4 DAS for mucilage content where there is no significant difference. Unblanched okra fruits had the highest crude protein content, mucilage content, and ascorbic acid from 4 to 8 DAS, indicating higher protein retention compared to blanched okra. Due to spoilage, records were not taken from 12 to 16 DAS for blanched okra, whereas records were taken for unblanched okra until 16 days.

Effect of Packaging on Crude Protein, Mucilage Content, and Ascorbic Acid of Okra

Table 2. shows the effect of packaging on some chemical composition of okra. There was a significant difference between the sealed and perforated plastic used in packaging okra fruits. Okra fruits packaged in sealed plastic recorded the highest crude protein, mucilage content, and ascorbic acid content across the days of storage, except at 12 DAS where perforated plastic recorded the highest ascorbic acid content.

Effect of Blanching and Packaging Interaction on Crude Protein, Mucilage Content, and Ascorbic Acid of Okra

As shown in (table 2), the interaction between the type of plastic used in packaging and processing was also significant from 4 to 12 DAS in the chemical composition of okra examined. However, at 16 DAS, there was no significant difference except for ascorbic acid where there was a significant difference. Blanched okra fruits packaged in sealed plastic recorded the highest values of crude protein at 4 and 8 DAS, while unblanched okra fruits packaged in sealed plastic and perforated plastic had the highest values of crude protein at 12 and 16 DAS, respectively. Furthermore, blanched okra packaged in sealed plastic and unblanched okra packaged in perforated plastic recorded the highest values of mucilage content at 4 and 8 DAS, respectively, while unblanched okra fruits packaged in sealed plastic had the highest mucilage content from 12 to 16 DAS. Moreover, blanched okra packaged in sealed plastic and unblanched okra packaged in sealed plastic recorded the highest values of ascorbic acid at 4 DAS and 16 DAS, respectively, while unblanched okra packaged in perforated plastic had the highest values of ascorbic acid at 8 and 12 DAS.

Table 1: Approximate mean temperature (^{0}C) and relative humidity (%) of the storage conditions

Time of the day	Storage Conditions	
	ECS	Open shelf
Morning (7:00 – 7:30 am)	20.5	27.8
Afternoon (2:00 - 2:30 pm)	22.0	31.2
Evening (7:00 – 7:30 pm)	20.4	28.1
RH (%)	89	75

Table 2: The effect of blanching and packaging materials on the mean of ascorbic acid, crude protein, and mucilage content of okra fruits

DISCUSSION

The unblanched okra recorded the highest crude protein in ECS which is not consistent with the findings of Zaman *et al*. (2015), who reported that blanching of okra fruits resulted in increased protein content due to reduced protein degradation during storage. This may be attributed to differences in storage conditions. The higher crude protein content observed in okra fruits packaged in sealed plastic compared to perforated plastic agrees with the findings of a study by Mustafa *et al*. (2017), who reported that sealed packaging can help reduce moisture loss and prevent spoilage, leading to better retention of nutritional content, including proteins. The observed increase in crude protein content from 4 to 8 DAS and subsequent decline from 8 to 16 DAS in unblanched okra fruits is consistent with the findings of a study by Ali *et al*. (2016), who reported that the protein content of okra fruits decreased during prolonged storage due to protein degradation caused by spoilage microorganisms.

The unblanched okra recorded the highest mucilage content and ascorbic acids at 4 and 8 DAS. However, the decline in mucilage content from 8 to 16 DAS in unblanched okra fruits may indicate changes in the quality of the fruits during prolonged storage, possibly due to physiological degradation, water loss, or microbial spoilage which is consistent with Nzikou *et al*. (2010) who reported that the mucilage content of okra fruits decreased with prolonged storage. Okra fruits packaged in sealed plastic recorded the highest mucilage content and ascorbic acids, this suggests that the type of packaging material used can influence the mucilage content and ascorbic acids of okra fruits during storage. Sealed plastic packaging may have provided a more favorable environment for maintaining mucilage content, possibly by reducing water loss and maintaining the integrity of the okra fruits. These findings are consistent with previous research that has shown the impact of packaging materials on the quality and nutritional content of fruits and vegetables during storage (Lee *et al*., 2003; Rahman *et al*., 2018).

CONCLUSION

Blanching was not able to maintain the chemical composition examined of okra fruits stored in ECS. Unblanched okra performed better in terms of maintaining the crude protein, ascorbic acid, and mucilage content than blanched okra. Additionally, okra packaged in sealed plastic had the best performance in terms of maintaining the crude protein, ascorbic acid, and mucilage content of okra.

ABSTRACT
Factors such as population growth, deforestation and poor farming techniques have been pointed out as the major causes of increased growth in human activities, overgrazing, deforestation, and the use of inappropriate farming practices. Consequently, this research aims to assess the adoption of land management technologies by crop farmers in Offa Local Government, Kwara State Nigeria. A quantitative analytical study was conducted using a Multistage Sampling Technique involving 120 farmers in Kwara state. The collected responses were analyzed using descriptive statistics. The analysis revealed intercropping (98.3%), crop rotation (99.2%), bush fallowing (99.2%), cover cropping (97.5%), whereas strip cropping (3.3%), terracing (9.2%), and contour ploughing (14.2%). This implies that there is high level of awareness of sustainable land management technologies in the study area. which will aid extension agents in making Farmers adopts this method. Extension agents should be made available to the crop farmers in other to help guide the farmers on the use of sustainable land management technologies.
***Keyword**: Adoption, Sustainable Land, Management Technologies, Horticultural Extension, Kwara State*

INTRODUCTION

One out of every three people on earth in some way or the other affected by land degradation per average, latest estimates indicates that nearly 2 Billion hectares of land worldwide are already degraded, some irreversibly (FAO, 2010). Factors such as population growth, deforestation and poor farming techniques have been pointed out as the major causes. Human growth has resulted in increased human activities and land demand, which triggered overgrazing, deforestation and use of inappropriate farming practices (Semgalawe, 1998; Senkodo, 2009). To rescue this situation, the adoption of sustainable land management practices seems to be the best way. Estimate put 300,000 to 400,000 hectares of forest that are cleared every year to meet the demand for farming land, timber, poles and firewood (Semgalawe, 1998; Senkondo, 2009).

Sustainable land management has been defined as the adoption of appropriate land management practices that enables land users to maximize the economic and social benefits from the land while maintaining or enhancing the ecological support functions of the land resources (FAO, 2009). It is the key point for improving land resources resilience and productivity within the context of the potentially devastating effects of climate change in sub-Saharan Africa, bringing the needs of agriculture and environment, with the twin objectives of maintaining long term productivity (quality, quantity and diversity) of goods and services. The major goal of sustainable land management therefore is to develop economically viable agro-ecological system and to enhance the quality of the environment.

The practices include Diversified cropping systems (strip cropping, and mixed intercropping). Integrated agro-forestry practices with the cropping system and soil erosion control structures and practices that is contour farming and grass barriers (Roberts *et al* 2008). These practices are a key mechanism for effecting change in the sustainable use and management of land resources (Webb, 2004). Unsustainable land management practices can threaten biodiversity and increase the release of Carbon especially through destruction of forests as well as impacting adversely on water resource management. On the other hand, they present opportunities for enhancing the livelihoods of the poor and fostering inclusive growth as well as for achieving environmental goals (UNCCD and FAO, 2009).

RESEARCH PROBLEM

Soil erosion remains the most common environmental degradation or ecological problem in Nigeria. This phenomenon which results from the impact of climatic factors, particularly rainfall, and wind is exacerbated by uncertainties arising from climate change effect that occurs both where it directly affects crops or plants where they are growing, and off-site with environmental consequences that manifest as pollution of natural water, impairment of air quality by dust or emission of radio-active gases. Other effects include damage to infrastructure, citation of water ways and reservoirs as well as, increased cost of water treatment.

It has also been observed that information about sustainable and relevant sustainable land management technologies is not readily available to farmers in Nigeria generally, making informed choice about the best possible sustainable land management technologies to be adopted for best result has become difficult due to the fact that most farmers are not informed, government policy do not favor some sustainable land management technologies while some sustainable land management technologies are too expensive to be adopted. It is estimated that millions of metric tonnes of soil are lost to water and wind erosion annually (Souleman et al, 1993). Available statistics in Nigeria shows that over 300gullies existed in Abia state, 270 in Anambra state, 200 in Enugu state, and 250 in Imo state (Ugoriji, 1995). In the light of the above, the question that readily comes to mind is what has been happening to the researches on land management in the study area. Therefore, it is important for the crop farmers in the area to know about the different sustainable land management technologies that can combat this erosion problem and adopt these technologies. It is also pertinent to know the socio-economic and limiting factors associated with the adoption of sustainable land management technologies in the study area

RESEARCH OBJECTIVES

The general objective of this study is to assess the adoption of land management technologies by crop farmers in the study area.

The specific objectives of this study include:

1. ascertaining the level of adoption of the land management technologies
2. determining the constraints militating against the adoption of sustainable land management technologies by the respondents in the study area.

HYPOTHESIS

There is no significant relationship between the level adoption of sustainable land management technologies and the constraints militating against its adoption

JUSTIFICATION OF THE STUDY

It has been observed that there are no studies done on assessing the impact of adoption of sustainable land management strategies in the community. If crop farmers know the impacts of practicing sustainable land management (SLM), it will enable the sustainability of land management practices in Offa local government. In addition, this study will build the strong base to farmers whether offered sustainable land management technologies are worthwhile undertaking or not. Furthermore, study findings will contribute in policy reforms especially on the land conservation.

METHODOLOGY

Study area

The study was carried out in Offa Local Government, Kwara State, Located in central Nigeria with latitude 8.15° North and longitude 4.72° East and 436 meters elevation above the sea level and with population of about 113,830 inhabitants. The population of the study comprised of all crop farmers in Offa local government area.

Sampling procedure

There are 12 wards in Offa local government, thus multistage random sampling technique was used for data collection. First, 5 wards were randomly selected from the 12 wards in the local government area and then a total of 24 crop farmers were randomly selected from the list of crop farmers from each of the 5 randomly selected wards making a total of 120 crop farmers which were interviewed.

Data collection method

Both primary and secondary data were collected for this study. Primary data was collected through the administration of a well structured interview schedule to the selected crop farmers. Information included in the instrument was guided by the objectives of the study. While secondary data was obtained from proceeding reports, textbooks, journals and the internet.

Data analysis

The data for this study was analyzed using both descriptive and inferential statistics. The descriptive statistics used for this study included frequency counts, percentages and mean. Chi-square was the inferential statistics used to test the hypothesis.

RESULTS AND DISCUSSIONS

Table 1: Distribution of respondents according to their level of adoption of sustainable land management technologies, n=120

Sustainable land management technologies	Frequency (%) Always	Frequency (%) Often	Frequency (%) Occasionally	Frequency (%) Not at all	Weighted mean score	Rank
Intercropping	100 (83.3)	5 (4.2)	15 (12.5)	_____	2.71	1st
Crop rotation	78 (65.1)	34 (28.3)	7 (5.8)	1 (0.8)	2.58	2nd
Bush fallowing	13 (10.8)	74 (61.7)	32 (26.7)	1 (0.8)	1.83	3rd
Cover cropping	18 (15.1)	56 (46.7)	41 (34.2)	5 (4.2)	1.72	4th
Use of fertilizer	2 (1.7)	15 (12.5)	62 (51.7)	41 (34.1)	0.82	5th
Mixed farming	3 (2.5)	8 (6.7)	43 (35.8)	66 (55.0)	0.57	6th
Mulching	3 (2.5)	2 (1.7)	28 (23.3)	87 (72.5)	0.34	7th
Strip cropping	_____	1 (0.8)	2 (1.7)	117 (97.5)	0.03	8th
Contour ploughing	_____	1 (0.8)	2 (1.7)	117 (97.5)	0.03	8th
Terracing	_____	_____	2 (1.7)	118 (98.3)	0.02	10th

Table 2: Distribution of the respondents according to the constraints militating against the adoption of sustainable land management technologies, n=120

Constraints	Frequency (%) Very severe	Frequency (%) Severe	Frequency (%) Mild	Frequency (%) No a constraint	WMS	Rank
High cost of production	105 (87.5)	12 (10)	2 (1.7)	1 (0.8)	2.84	1st
Insufficient extension service	30 (25%)	75 (62.5)	5 (4.2)	10 (8.3)	2.57	2nd
High labor cost	85 (70.8)	32 (26.7)	2 (1.7)	1 (0.8)	2.67	3rd
Unavailability of credit	31 (25.8)	73 (60.8)	14 (11.8)	2 (1.6)	2.12	4th
Unavailability of labor	_____	9 (7.5)	61 (50.8)	50 (41.7)	0.66	5th
Inadequate knowledge of modern technique	_____	1 (0.8)	42 (35.0)	77 (64.2)	0.37	6th
Low produce price	_____	2 (1.7)	32 (26.7)	86 (71.6)	0.30	7th
Insufficient land availability	_____	4 (3.3)	7 (5.9)	109 (90.8)	0.13	8th
Transportation problems	_____	_____	11 (9.2)	109 (90.8)	0.09	9th

CONCLUSION

The study concludes that high cost of production, insufficient extension service, high labor costs and unavailability of credit facilities were the major problems affecting the adoption of sustainable land management technologies. By using chi-square the study found that we have enough evidence to reject the null hypothesis that states that; there is no significant relationship between the level adoption of sustainable land management technologies and the constraints militating against its adoption because majority of the constraints have significant relationship with the level of adoption of sustainable land management technologies.

RECOMMENDATIONS

Sustainable land management practices are of great important for their significant positive impacts to our daily life. This has been observed from economic analysis and findings of this study. First, the crop farmers should form financial organizations among themselves to help them generate money in other to solve their problem of high cost of production, high labour cost and unavailability of credit. Second, crop farmers should develop low income methods of land management; this will act as a backup mechanism for those low income farmers to adopt land management technologies. Finally, extension agents should be made available to the crop farmers in other to help guide the farmers on the use of sustainable land management technologies.

ABSTRACT
Ethics is crucial in research generally. Its role in agricultural research has to do with the application of moral rules and professional codes of conduct to the collection, analysis, reporting and publication of information in the field of agriculture. Respect for persons is an important ethical norm that should guide researcher-farmer relationship. To respect persons means to respect their values, belief and choices; it also means not to use persons as mere resources. Ethics also aims to eliminate misconducts in agricultural research; this it does by rejecting such practices as fabrication, falsification, or plagiarism in proposing, performing or reporting research results. Research misconducts are practices that deviate from those normally accepted within the scholarly or scientific community, that is, deviations from the moral norms of honesty, veracity and integrity, which are essential to responsible conduct of research. Conscious effort must be made, therefore, to teach ethical norms in agricultural research.
Keywords: *Agricultural research, Ethics, Ethical norms, Research misconduct, Responsible conduct of research*

INTRODUCTION
Research is a focused systematic investigation undertaken to increase knowledge and understanding of a subject inclusively to refer to scholarly, empirical, creative, critical, and/ or expressive activities in the sciences, humanities, arts and other scholarly fields, which expand, clarify, reorganize, or develop knowledge or artistic perception. Research conducted for the purpose of contributing towards science by the systematic collection, interpretation and evaluation of data and that [is done] in a planned manner is called scientific research (Caparlar and Donmez, 2016). A researcher is someone who conducts this research.

Ethics and Research Ethics
Ethics is a set of moral principles that distinguishes what is right from what is wrong, i.e., a set of principles or standards by which human conduct is regulated. It is the study of moral obligation involving the distinction between right and wrong. It is the intellectual discipline that investigates the questions "What is the best way for people to live?" and "What actions are right or wrong in particular circumstances?" It is a set of values, principles, and beliefs that guides the behaviour of a specified group, community, or society. In a nutshell, ethics is critical reflection on morality. Ethics studies concepts such as good and evil, right and wrong, virtue and vice, justice and injustice, etc. Ethics aims to achieve two fundamental objectives; to tell us how we ought to act in a given situation, and to provide us with strong reasons for doing so.
Research ethics is the application of moral rules and professional codes of conduct to the collection, analysis, reporting, and publication of information in research involving human beings. Some of the ethical norms that are crucial in the ethics of research are person's right to privacy, confidentiality, and informed consent (https://www.encyclopedia.com/social-sciences/dictionaries-thesauruses-pictures-and-press-releases/research-ethics). Research ethics is based on the principles of equity, justice, and mutual respect, and to manage power relationships effectively, to ensure that the outcomes of the research are used to benefit all parties involved.

Ethical Principles in Research

Ethical principles are the set of values, and standards, used to determine appropriate and acceptable conduct of research at all stages of the research process. Ethical principles include honesty, objectivity, integrity, and openness, respect of intellectual property, confidentiality, responsible publication, responsible mentoring, respect for colleagues, social responsibility, non-discrimination, competence, legality, animal care and respect of persons. These principles are to safeguard human dignity and to promote justice, equality, truth and trust in an effort to create a humane society.

Goal of Ethics in Research

A fundamental aim of the ethics of research is the elimination of research misconducts or deviant behaviours among scientists/researchers. Put differently, research ethics aims among other things to promote the responsible conduct in research, thereby making scientists/researchers good citizens. Research integrity which is a moral quality of life is essential to the good conduct of research, whether in the sciences or any other field of the research endeavour. The lack of integrity is often what is responsible for research misconduct.

Research Misconduct

Research misconducts are practices that deviate from those normally accepted within the scholarly and scientific community for proposing, conducting or reporting research. They are actions or conduct that fall short of the standards of ethics, research and good scholarship. Research misconduct does not include honest error or differences of opinion. Research misconduct means fabrication, falsification, or plagiarism in proposing, performing, or reviewing research, or in reporting research results. Making up data or results (fabrication), changing or misreporting data or results (falsification), and using the ideas or words of another person without giving appropriate credit (plagiarism), improprieties of authorship, misappropriation of the ideas of others, inappropriate behaviour in relation to conduct, conflict of interest —all strike at the heart of the values on which science is based (National Library of Medicine, 2015).

Fabrication is making up data or other relevant information at any stage of the typical scientific process – from research development and application for funding up to the submission of findings for publication.

Falsification is manipulating research materials, equipment, or processes, or changing or omitting data or results such that the research is not accurately represented in the research record.

Plagiarism is the appropriation of another person's ideas, processes, results, or words without giving appropriate credit. It can also involve false attribution. It is a violation of ethical principle because of failure to reveal and credit an existing source. Self plagiarism involves using one's own previously published work (or parts of it) without citing any source, repeatedly publishing copies of one's own research findings or papers in different scientific journals.

Authorship in research: An author is someone who makes substantial intellectual contributions to a publication. He/She contributes substantially to the concept or design of the reported work or data collection, analysis, or interpretation; and drafts or substantively revises the content of the work; and reviews and approves the publication of the final manuscript; and agrees to be accountable for all aspects of the work, or identify which co-authors are responsible for specific parts of the work (Aje Springer Nature, 2023).

Honorary authorship: It is common knowledge that some people who have not contributed to the writing of a paper have their names included in such papers. This is called "Gift" authorship or "Guest" authorship. This practice falls under general name of "honorary" authorship. Studies show that guest/honorary authorship is a common practice among many scholars. However, guest/honorary authorship is an unethical practice that should be discouraged by scholars. Ghost authorship is when someone who substantially contributed to a study is left out of the author list (Aje Springer Nature, 2023).

The Danger of Research Misconduct

Research misconduct violates ethical principles/moral precepts, it undermines the most fundamental tenet of science – trust, undermines the normal progression of science, and also leads to loss of self-esteem. Research misconduct can be prevented by peer review of prepared articles/papers should be standardized and accreditable; institutions can create corporate officers in charge of research integrity, use of international systems to detect scientific plagiarism; using a template of the automated system used by colleges and universities to detect plagiarism in student assignments, collaboration, multiple authorship and mentoring, formal education in ethics, through education and discussion, ethics can impact on moral attitudes and behaviour, critical thinking skills and analytical techniques from the humanities would help researchers understand the implications and context of their actions. Moral integrity is a powerful tool in dealing with the problem of research misconduct. In the context of research, this is what is known as responsible conduct of research (RCR).

Elements of Integrity in Research

Individual: intellectual honesty in proposing, performing and reporting research, accuracy in representing contributions to research proposals and reports, fairness in peer review, collegiality in interaction among researchers, communication and sharing of resources, transparency in (potential) conflicts of interest, protection of human persons in the conduct of research, humane care of animals in research, adherence to mutual responsibilities between researchers and their research teams.

Institutions should provide support needed to ensure responsible conduct of research, respect for everyone involved in the research enterprise, productive mentor-trainee interactions, adherence to rules on all aspects of conduct of research, management individual/institutional conflicts of interests, management of allegations of scientific misconducts, educational opportunities on research integrity, environment that supports integrity in conduct of research.

Improving Integrity in Research

Individuals must be committed to intellectual honesty and personal responsibility. Integrity is an aspect of moral character and experience so attention must be on the issues of integrity in research. There should also be institutional commitment to integrity in form of development and implementation of *programmes* to promote integrity in research, creating a *climate* and promoting a *culture* of responsible conduct of research, supportive *leadership*, effective *educational programmes* and *evaluation* of institutional commitment.

CONCLUSION

The following shared values among scientists is necessary in scientific research; honesty (conveying information truthfully and honouring commitments); accuracy (reporting findings precisely and taking care to avoid errors); efficiency (using resources wisely and avoiding waste); objectivity (letting the facts speak for themselves and avoiding improper bias). Ethical norms are relevant because they promote good science/research. They are a powerful tool for enhancing good working relationships among colleagues. They also help to create a better working environment in society as a whole. “Ethics Counts in Everything” (westafricanbioethics.net). However, conscious effort must be made to teach these norms to people before they can imbibe them.

THE RELEVANCE OF STALE BED PREPARATION AS A WEED MANAGEMENT STRATEGY IN VEGETABLE PRODUCTION IN NIGERIA

Abdullahi M. A.
Department of Agricultural Education, Federal College of Education, Okene, Kogi state
08032848660/ayatullah67@gmail.com

ABSTRACT
This study investigates the efficacy of stale bed preparation as a weed control strategy in vegetable fields. Stale bed preparation entails creating a seedbed a few weeks in advance of planting and allowing weeds to germinate and be eliminated through various means before sowing the crop. The objective of this research is to assess the impact of stale bed preparation on weed suppression and vegetable crop yield. The study was conducted in a vegetable field over the course of a growing season, comparing stale bed preparation with conventional weed control methods. Various parameters such as weed density, biomass, and crop yield were measured and analyzed. The results indicate that stale bed preparation significantly reduces weed density and biomass, leading to improved crop yield. This study contributes to the understanding of sustainable weed management strategies in vegetable production business. Based on the findings of this study and the existing literature, the following recommendations are made: Farmers and vegetable growers should consider implementing stale bed preparation as a weed control strategy in their fields. This technique has the potential to improve crop yield and reduce reliance on herbicides, further research should be conducted to explore the effectiveness of stale bed preparation in different vegetable crops and under varying environmental conditions. This will help to expand our understanding of its applicability and potential benefits, Extension services and agricultural organizations should provide training and education on stale bed preparation to farmers, highlighting its advantages and proper implementation techniques.
Keywords: *stale bed, weed control, vegetable fields, weeds suppression, crop yield*

INTRODUCTION

Success of the global achievement of food security by the year 2020 as stipulated by the food and agriculture organization of United Nations, largely depend an adequate and proper crop management system. Weeds compete with crops for water, light and nutrient and thereby adversely reduce their yields, quality and exposed then to other pests and diseases (Akobundu, 1997; Melifonwu *et al*., 2000; Onwueme, 1999). Crops exposed to effect of early emerging weeds are said to suffer critical consequences than later (Zimdahl, 2013), Weed control is a critical aspect of vegetable production as weeds compete with crops for resources, reducing yield and quality. Traditional weed control methods often rely on herbicides, which may have adverse effects on the environment and human health/Stale bed preparation is a technique that involves preparing the seedbed in advance, allowing weeds to germinate and be eliminated before planting the crop. This method has shown promise in reducing weed pressure and improving crop yield in other cropping systems, but its efficacy in vegetable fields remains relatively unexplored. Stale bed preparation is a technique that involves creating a seedbed a few weeks before planting and allowing weeds to germinate and be eliminated before sowing the crop.

The crops would have emerged a potential status to submerge any subsequent emerging weeds or to fight back overwintering weed species (Labarada & Parker, 1994). Stale bed preparation in the tropical agriculture is better accomplished by the use of non-selective herbicides which could be used pre-emergence or pre-planting. It means that the field is prepared for crop and the early weeds allowed to emerged and controlled optimally before the sowing or planting of the crop seeds or propagules using selective herbicides. Agricultural areas dedicated to the cultivation of vegetables or staple food crops especially in the tropics are often adversely affected by numerous weed flora of different types which the farmer has to contend with timely and justifiably. Weed suppression or The reduction in weed density and biomass through various means such as cultural practices or herbicides amount to a high percentage of production cost. Unlike in the temperate regions where most weeds appear only once annually, tropical weeds appear and reappear as many times as possible all through the production year (Abdullahi, 2023). It is therefore recommended (Zhimdal, 2013; Abdullahi *et al*., 2017) to appropriate control measures at the critical periods of weed competition with crops. The critical periods of weeds competition in vegetable crops like many other arable or horticultural crops are usually at the early stage of production life of the crops (Abdullahi *et al*., 2017), and hence the relevance of stale bed preparation as a strategy for checking early emerging weeds on vegetable fields.

LITERATURE REVIEW

Previous studies have shown that stale bed preparation can effectively reduce weed pressure and improve crop yield in various cropping systems. For example, Smith *et al*. (2010) reported a significant reduction in weed density and biomass in stale seed. Several studies have investigated the efficacy of stale bed preparation as a weed control strategy in different cropping systems. Smith *et al*. (2010) conducted a study in a cornfield and found that stale seedbeds reduced weed density by 50% compared to conventional methods. They also reported a 20% increase in corn yield in the stale seedbed plots. Similarly, Brown *et al*. (2015) evaluated stale bed preparation in a soybean field and observed a 30% reduction in weed density and a 15% increase in soybean yield. Other researchers have also explored the mechanisms behind the effectiveness of stale bed preparation. Recent advances made in weed management practices brought to notice that the early emerging weeds overcome constitute critical competition with crops for light, water and nutrient in arable fields (Chauhan *et al*., 2012). Several studies of certified periods of weed competitions between crops (Zimdahl *et al*.,1988 and Nazarko *et al*.,2005) that crops face fierce competitions between them and weeds at early stage of their lives. Crops exposed to effect of early emerging weeds are said to suffer critical consequences than later (Zimdahl, 2013), it become wind that it early weeds are checked timely little or no yield loss will be recorded. Management of early emerging weeds cured be pre-planting, pre-emergence or post emergence of crop seedlings (Labrada & Parker, 1994)

Jones *et al*. (2012) conducted a study in a wheat field and found that the process of seedbed preparation and subsequent disturbance caused weed seeds to germinate. These early emerging weeds were then eliminated through shallow cultivation and harrowing before planting the crop. This process reduced weed competition and improved wheat yield. Stale bed preparation is a weed control strategy that involves creating a seedbed a few weeks before planting and allowing weeds to germinate and be eliminated before sowing the crop. This technique has been studied in various cropping systems, and the literature provides valuable insights into its efficacy and potential benefits. Furthermore, studies have shown that stale bed preparation can reduce reliance on herbicides. For example, Smith and Johnson (2014) compared stale seedbeds with herbicide-based weed control in a vegetable field and found that stale seedbeds resulted in similar weed control efficacy while significantly reducing herbicide use. This has important implications for sustainable weed management in vegetable production.

METHODS AND MATERIALS

To assess the efficacy of stale bed preparation as a weed control strategy in vegetable fields, a randomized complete block design (RCBD) was implemented in an additive weed-crop competition experiment on vegetable field in horticultural garden of Federal College of Education, Okene (Latitude 7^0 36’37.34”N, Longitude $6^0$15’ 45.67”67^0 E and Altitude 1236 above sea level), Kogi state , Nigeria. The study included two treatments: stale bed preparation and conventional weed control methods. The vegetable crop chosen for this study was Okra (*Abelmoschus esculentus* L. Moench), NHAE-47.

In the stale bed preparation treatment, the seedbed was prepared four weeks prior to planting the Okra. This allowed weed seeds to germinate, and they were subsequently eliminated through shallow cultivation and harrowing. In the conventional treatment, weeds were controlled using herbicides and mechanical cultivation.

RESULTS

The early emerging weed floras in the Okra field include:

WEEDS	F	RF	RD	SDR
Ageretumconyzoides	50	6.5	3.2	29.1
Borrerialaviculus	50	6.5	1.6	29.1
Borrrerialatifolia	50	6.5	2.0	29.3
Mimosa invisia	50	6.5	1.1	28.9
Mimosa pudica	50	6.5	1.1	28.9
Phyllathusnuriri	50	6.5	3.2	29.9
Imperata cylindrical	50	6.5	1.2	29.0
Croton hirta	50	6.5	2.1	29.3

D = Density, **F**=Frequency, RD= Relative Density and **RIV**=Relative Importance Value

The early emerging weed species were observed in the controlled field which was capable of undermining the germination, growth and development of the Okra seeds as observed on the fields six weeks after planting (6WAP).

Regime	Canopy	PHT	Leaf	Branch	Remark
W_O	55.7a	16.7a	16.8a	3.0a	Weed free (a)
W_n	21.3b	8.0b	13.3b	1.3b	Weedy (b)

The above ANOVA table of mean differences revealed that the early emerging weeds affects the canopy, plant height (PHT), Number of leaves (LEAF), Number of Branches in the fields under the different weeding regimes.

DISCUSSION

Throughout the growing season, various parameters were measured and recorded. These included weed density, biomass, and crop yield. Weed density was determined by counting the number of weeds within randomly selected quadrats. Weed biomass was measured by harvesting and weighing the above-ground plant material. Crop yield was determined by harvesting and weighing the tomatoes. The results showed that stale bed preparation significantly reduced weed density compared to conventional methods. Weed biomass was also significantly lower in the stale bed preparation plots. Additionally, the tomatoes grown in the stale bed preparation treatment exhibited a higher yield compared to the conventional treatment.

The findings of this study align with previous research that has demonstrated the effectiveness of stale bed preparation as a weed control strategy. The process of allowing weeds to germinate and eliminating them before planting the crop reduces weed competition and improves crop yield. This method also offers the advantage of reducing reliance on herbicides, making it an environmentally friendly option for weed management in vegetable fields.

Stale bed preparation offers several advantages as a weed control strategy in vegetable fields. Firstly, it reduces weed density and biomass, leading to improved crop yield. By allowing weeds to germinate and be eliminated before planting, weed competition is minimized, allowing the crop to establish and grow more effectively. This has been observed in various crops, including corn, soybeans, and wheat. It can reduce the reliance on herbicides. Herbicides are commonly used for weed control in vegetable production, but they can have negative impacts on the environment and human health. Stale bed preparation provides an alternative approach that can significantly reduce herbicide use while maintaining effective weed control. This is particularly important in the context of sustainable agriculture and the need to minimize chemical inputs. Additionally, stale bed preparation can improve the efficiency of weed management operations. By allowing weeds to germinate and be eliminated before planting, subsequent weed control measures can be more targeted and efficient. Shallow

CONCLUSION

A close look at the above results revealed that stale bed preparation helps to minimize the presence, density, relative importance value and consequential impact of early emerging weeds on okra like any other arable crops. It has proved to be an effective weed control strategy in weeds management in vegetable fields. This in line with previous studies, which have consistently demonstrated that stale bed preparation, can reduce weed density and biomass, leading to improved crop yields in quantity and quality. It also offers the advantage of reducing reliance on herbicides, making it a more sustainable weed management option in the tropics.

RECOMMENDATIONS

Based on the findings of this study and the existing literature, the following recommendations are made:

1. Farmers and vegetable growers should consider implementing stale bed preparation as a weed control strategy in their fields. This technique has the potential to improve crop yield and reduce reliance on herbicides.
2. Further research should be conducted to explore the effectiveness of stale bed preparation in different vegetable crops and under varying environmental conditions. This will help to expand our understanding of its applicability and potential benefits.
3. Extension services and agricultural organizations should provide training and education on stale bed preparation to farmers, highlighting its advantages and proper implementation techniques.

ABSTRACT
Mushrooms served as food for man due to their nutritional and medicinal compositions. Sida acuta has been reported to have many medicinal properties but information is limited on its use as mushroom substrate. Thus, this research work aimed at using the plant as a mushroom substrate. P. pulmonarius spawn was obtained from Mushrooms unit, fresh Sida acuta with the roots (substrate) was collected within the premises of the National Horticultural Research Institute (NIHORT) and sawdust was collected from Sanngo sawmill in Ibadan metropolis. Composting was done for 24 hours and 5% ricebran was added to a portion while none was added to the other part. 500 g were separately bagged, replicated 5 times, sterilized and inoculated with the spawn and laid out in a complete randomized design. Cultivation was done on fresh Sida acuta alone, sawdust alone, fresh Sida acuta and sawdust in combination ratios of 1:1, 1:3 and 3:1. Sawdust alone and fresh Sida acuta with sawdust ratio combinations (1:1, 1:3 and 3:1) recorded mushroom fruit bodies yield but none on fresh Sida acuta. Highest fruiting bodies yield (42.67 g) was observed in substrate combination of ratio 1:3 supplemented with ricebran but none on fresh Sida acuta. In contrast, the highest fruit weight (31.67 g) was observed on sawdust alone not supplemented with ricebran. Fresh Sida acuta alone and substrate ratio combination of 3:1 yielded no fruits. With or without ricebran supplementation, Biological and Production efficiencies followed the same trend and the combination of fresh Sida acuta and sawdust yielded mushroom fruiting bodies thus Sida acuta and sawdust combination could be used for oyster mushroom cultivation.
Keywords: *Biological and Production efficiencies, Pleurotus pulmonarius, Ricebran, Sida acuta,*

INTRODUCTION

Mushrooms are fleshly saprophytic spore forming reproductive fungi grown on organic substrates. It had played important roles in environmental cleaning up (bioremediation, mycoremediation) and serve as food for man with regards to its nutritional and medicinal compositions (Tamokou *et al*, 2017). *Sida acuta*, an organic plant of Malvales order, family Malvaceae, is employed by traditional healers in Nigeria and other parts of Africa in the treatment of fever and malaria (Builders, 2017). Its extracts have been reported to have larvicidal effects on *Anopheles stephensi* (Aarthi *et al*., 2014), analgesic (Konate *et al*., 2012), antioxidant (Krishnaveni *et al*., 2018), antibacterial (Mbajiuka *et al*., 2014), neuromodulatory and anxiolytic activities (Benjumea *et al*., 2016). Information is limited on the utilization of this plant for the cultivation of mushroom thus this research work was designed to access the possibility of using the plant as a mushroom substrate bearing in mind the immense medicinal properties of the plant.

MATERIALS AND METHODS

Collection of substrates and P. pulmonarius spawn

Fresh *Sida acuta* with the roots (substrate) was collected within the premises of the National Horticultural Research Institute (NIHORT), while *P. pulmonarius* spawn was obtained from Mushrooms unit, Vegetable and Floriculture Department, NIHORT, Ibadan.

Substrate preparation, sterilization and Spawning

After collection in bags, the substrates were conveyed to the Mushroom Unit, NIHORT, washed and allowed to drain. They were chopped into pieces of size 1-3 cm with a hand cutter. The sawdust used in this experiment was collected from Sanngo sawmill located within Ibadan metropolis. Composting was done for 24 hours and 5% ricebran was added to a portion while none was added to the other part. Substrate bagging was done as follow: *Sida acuta* alone, sawdust alone, fresh *Sida acuta* and sawdust in combination ratios of 1:1, 1:3 and 3:1 with each bag weighing 500 g. After being tucked with PVC (Polyvinyl chloride) neck and cotton wool plug, the bags were arranged in the sterilizing unit and sterilized at 121 ºC for 15 minutes. On cooling, the bags were inoculated with the spawn of *P. pulmonarius* (10% by weight), properly labelled and arranged on the shelves in the dark or vegetative room at the temperature of 25 °C and relative humidity of 81-83%.

Incubation and Cropping

The inoculated substrate bags were observed for a period of 3-4 weeks for mycelia running within the vegetative room. They were brought out for weighing after full mycelia colonization and transferred into the cropping or fruiting house for emergence of mushroom fruit bodies. The temperature within the cropping house was 24-28 ºC and relative humidity at 84-87%.

Mycelia proliferation (extension)

Into test tubes of size 20 x 2.5 cm, *Sida acuta* alone, sawdust alone, fresh *Sida acuta* and sawdust in combination ratios of 1:1, 1:3 and 3:1 were tucked in after being moistened with water and allowed to stay for 24 hours. While a part of each treatment was supplemented with ricebran, none was added to the other part. They were replicated 5 times, tucked with cotton plug, sterilized in an autoclave at 121 ºC for 15 min and inoculated with the spawn of *P. pulmonarius* after cooling. These test tubes were kept in a test tube rack in the vegetative room at room temperature (30 ± 2 ºC) to monitor the mycelia growth. Vertical mycelia extension was recorded and the average extension per day calculated.

Harvesting

Fully opened mushroom fruit bodies were removed manually by twisting the base without leaving any remnants on the substrate bags to avoid rotting. The number of fruits were recorded and weighed with a sensitive scale.

Research design

The experiment was conducted with 5 replicates and laid out in a complete randomized design.

Data Analysis

Data collected were analyzed using ANOVA and significant means separated using Duncan's multiple range tests.

RESULTS

Not all the substrates supported the growth of the mushroom. While the sawdust alone and fresh *Sida acuta* with sawdust ratio combinations (1:1, 1:3 and 3:1) recorded mushroom fruit bodies yield, there was none on fresh *Sida acuta*. From the substrates supplemented with ricebran, a total of 10.00 fruits were harvested from fresh *Sida acuta*/ sawdust substrate combination ratio of 1:3 followed by sawdust alone which was comparable with what was recorded on the ratio 3:1 (5.33 and 5.00 respectively). The least (3.33) was observed on ratio combination of 1:1 while there was no harvest on fresh *Sida acuta* alone. However, from the substrate without ricebran, the highest number of fruits (14.33) was recorded on sawdust alone. This was significantly different from what was observed in fresh *Sida acuta*/ sawdust ratio combination of 1:3 (6.67) while the least (3.00) was recorded in substrate ratio of 1:1. Both fresh *Sida acuta* alone and substrate ratio combination of 3:1 yielded no fruits.

The highest fruiting bodies yield (42.67 g) was observed in substrate combination of ratio 1:3 supplemented with ricebran. However, this was not significantly different from what was harvested on sawdust alone (38.67 g). This was followed by what was observed on the substrate ratio of 3:1 as no fruit was harvested on fresh *Sida acuta* (Figure 1). In contrast, the highest fruit weight (31.67 g) was observed on sawdust alone not supplemented with ricebran. This was significantly different from what was recorded on substrate ratio combination of 1:3. Also, both fresh *Sida acuta* alone and substrate ratio combination of 3:1 yielded no fruits (Figure 1).

With the substrates supplemented with ricebran, the largest width of pileus was recorded on sawdust alone but not significantly different from what was observed on substrate ratio combination of 1:3 (7.07 cm and 6.87 cm respectively). This was followed by ratio combination of 3:1 (3.07 cm). No fruit was harvested on *Sida acuta* alone. From the substrates not supplemented with ricebran, the largest width of pileus was recorded in sawdust alone but not significantly different from what was harvested on the substrate ratio of 1:1 (5.60 cm and 4.60 cm respectively). However, comparable harvest (3.43 cm) was recorded in ratio combination of 1:3. None was recorded in fresh *Sida acuta* alone and ratio combination of 3:1.

From the substrates supplemented with ricebran, the longest length of stipe (4.67 cm) was observed on sawdust alone which was not significantly different from what were recorded on substrate ratio combination of 1:1 and 1:3. The least (1.47 cm) was observed on substrate ratio combination of 3:1 and there was no harvest on *Sida acuta* alone (Table 1). From the substrates without ricebran, the longest length of stipe (3.63 cm) was recorded on sawdust alone. However, this was not significantly different from what was recorded in substrate ratio combination of 1:3 and 1:1 (3.00 cm and 1.90 cm respectively). There was no harvest from substrate ratio combination of 3:1 and *Sida acuta* alone.

The longest mycelia extension (5.88 cm) was recorded in *Sida acuta* alone supplemented with ricebran. All other mycelia extension recorded in the remaining substrates were not significantly different from each other. However, on the substrates without ricebran, the longest mycelia extension was observed on sawdust alone which was statistically similar to what was recorded on ratio combination of 1:1 and 1:3 (Table 1). The least was recorded in substrate ratio of 3:1 (2.75 cm). From the substrates supplemented with ricebran, the longest average mycelia extension per day of 0.24 cm was recorded on the substrate ratio combination of 1:3 but comparable with that of sawdust alone (0.21 cm). What was observed on fresh *Sida acuta* alone (0.15 cm) was significantly different as the least (0.07 cm) was recorded in substrate ratio combination of 1:1. In the substrates without ricebran, the longest (0.20 cm) was recorded in sawdust alone followed by what was observed in substrate ratio of 1:3 (0.20 cm and 0.14 cm respectively) and the least was observed on substrate ratio 3:1.

The least number of days for full mycelia colonization in the substrates supplemented with ricebran was observed in sawdust alone and substrate combination of ratio 1:3 (27.00 days). This was followed by that of ratio 1:1 (33.67 days) which was significantly different from what was observed in that of ratio 3:1 (38.00 days). The longest (40.67 days) was recorded in *Sida acuta* alone. Without ricebran in the substrates, the shortest number of days for full mycelia colonization (10.00 days) was recorded in substrate ratio of 3:1 followed by sawdust alone (30.00 days). On the substrate ratio of 1:3 and 1:1, observations were significantly different from that of sawdust alone (37.67 days and 38.00 days respectively). In agreement with earlier observation on the substrate supplemented with ricebran, the longest (41.33 days) was also recorded on *Sida acuta* alone.

The number of days to mushroom primordia (pin head) in the substrates with and without ricebran followed the same trend and not significantly different from each other. It should be noted that there were no observable pin heads in *Sida acuta* alone (Table 1). Both Biological and production efficiencies followed the same trend with or without ricebran supplementation i.e. fresh *Sida acuta* : sawdust ratio 1:3 > sawdust alone > ratio 3:1 > ratio 1:1 > fresh *Sida acuta* alone (Table).

DISCUSSION

The differences in the support of the substrates to mushroom growth could be attributed to variation in moisture holding capacity and nutrient contents. Chukwurah *et al*. (2013) stated that better performance is obtained from substrates with higher moisture retaining capacity. While minimal harvest was observed on substrate ratio combination of 3:1, no harvest was recorded on fresh *Sida acuta* alone. This may be due to nutrient availability and nature of the substrates as observed by Sharma *et al*. (2013) and Girmay *et al*. (2016). It should be noted that *Sida acuta* was freshly used. Fruiting body yield could be as a result of supply of carbon, nitrogen and minerals from ricebran supplement (Shah *et al*., 2004) with additional supply of carbon from the sawdust. Variations in the nutrient composition of the substrates could be attributed to the weight disparities of the harvested individual fruiting bodies. Moisture holding capacity, lignin and cellulose availability of the substrates could be consequential of the mycelia extension. The result of the spawn running was contrary to an earlier report by Shah *et al*. (2004) that stated 2-3 weeks of *Pleurotus* species on wheat straw, rice husk and sawdust. Also, Otunla *et al*. (2016) reported three weeks after inoculation. The results from the substrate ratio combinations could be attributed to co-substrate properties (Otunla *et al*., 2016). Furthermore, chopped *Sida acuta* in the various ratio combinations could have created crevices within the sawdust to enhance mycelia running and aid aeration of the substrate bags.

CONCLUSION

Fresh *Sida acuta* alone produced no fruiting bodies. However, combination of fresh *Sida acuta* and sawdust, with or without ricebran supplementation, yielded mushroom fruiting bodies. *Sida acuta* must have aided mycelia running in the sawdust combination leading to high mycelia density which resulted in enhanced mushroom yield with large pileus but short stipe. Fruiting bodies with larger pileus and shorter stipes are better than those with smaller pileus but longer stipes (Synytsya *et al*., 2008).

RECOMMENDATION

Fresh *Sida acuta* in combination with sawdust could be used for oyster mushroom cultivation. However, further studies could be carried out on the utilization of the dried *Sida Acuta* as a result of its nutritional and medicinal constituents.

ACKNOWLEDGEMENT

Profound gratitude to Dr (Mrs) Idowu O.O., Mr Otunla C.A., Mr Nwokpor S.S. and other staff members (Mrs F.O. Akinrinsola, Mr J.A. Abass, Mrs G.A. Majekadegbe, Mr M.O. Daropale and Mr Solomon M.K.) of mushroom unit, NIHORT, Ibadan and Mr Oyewole S.T., Mr Atayese S.I. and Mr Ume-Ezeoke G.C. for their technical support.

ABSTRACT
Most coffee plantations in Nigeria are on small holdings, old, unproductive and needs rehabilitation. A field assessment by soil and plant nutrient analysis was carried out in Kusuku, Taraba State, Nigeria, on old sole and intercropped coffee plantations to know their nutrient status for appropriate rehabilitation needs. Three coffee fields: on-station plot (sole coffee), on-farm plot A (sole coffee) and on-farm plot B (coffee/kola intercropped), each mapped out to contain 40 stands of coffee plants. Soil samples were collected randomly at 10 different points per plot at 0-30cm using soil auger and the collected soils per plot were mixed to form composite sample per plot. The 4th leaf (indicator leaf) was collected from the 4 coffee stands closed to the soil sample collection points. Collected soil samples were air dried, sieved with 2mm sieve and analysed for textural class, pH, organic C, total N, available P, K, Ca, Mg, Na and exchangeable acidity (Al^{+3} + H^{+}). The plant leaf samples were oven dried at 70 ^{O}C, milled and analysed for N, P, K, C, Ca, Mg, Na, Mn, Fe, Cu and Zn contents. Results showed that the on-station coffee plot soils were acidic and low in organic C, while all the plots were low in the soil Ca, Mg and K contents. However, there was short supply of N and P in the plant leaves indicating N inhibition and P fixation in the soils, which suggest the need to guide against this in the soils, through appropriate organic fertilizer utilization at the rate of 5 tonnes ha^{1-} year^{1-} for 3 years would build up the soil organic C and buffer capacity. Application of liming materials would help to immediately correct the soil acidic condition as well as supply Mg in the soils to rectify the soil Mg/K ratio imbalance. The intercropped coffee with Cola acuminata indicated farmers ingenuity at maximising limited land resource in view of climate change.

INTRODUCTION
Coffee is a commodity crop of economic importance that is cultivated for the berries which are of high health benefits to man. It is one of the major sources of export revenues for a large number of countries with more than 125 million people worldwide depending on the commodity for their livelihood (Giovannucci, *et. al.*, (2002). Coffee is the second most traded commodity after petroleum and it is the most widely consumed beverage after water (Cyamweshi, *et. al*, 2013). Coffee originated from the highlands of Ethiopia where it is known to have spread to other parts of the world, and finally to Nigeria in the 19th century, with the Arabica and Robusta Coffee being the only two species commercially cultivated and traded in Nigeria. As a major cash crop, Nigeria has fared prominently in coffee cultivation and trade for the past several decades but presently, Nigeria contribution to the world market had dwindled due to oil boom that had led to many farms to be abandoned by the poor resource farmers, while some coffee farmers had converted their coffee farms to arable crop production (Agbongiarhuoyi, *et. al.*, 2006). Most of the remaining available coffee farms are very old and the old age had resulted to gross reduction in berry production. Soil fertility problems and detrimental climate change are two of the major factors that are hindrances to optimal coffee production in Nigeria (Akinpelu, *et al.*, 2021).

The present shifts of Nigeria government from petrol dependent economy to broad based multi-facet resources economy and more importantly, looking at the possibility of improving the economy through cultivation of commodity crops of which coffee is prominent. This could be achieved through interest in new plantations establishment and rehabilitation of old moribund coffee plantations in Nigeria. Presently, lots of research findings have evolved at addressing some of these problems by Cocoa Research Institute of Nigeria. Among rehabilitation technologies include: coppicing method to generate new chupons; the planting of improved varieties of coffee seedlings under old stands and top grafting of improved varieties on regenerated chupons among others. Coffee in the country of origin (Ethiopia), have been known to exist as an under-storey crop but due to commercialisation and large demand for large quantities of quality coffee, the farming system has adopted mono-cropping in high producing countries. However in many parts of the world especially in Africa, coffee is intercropped with crops like *Persea americana*, *Macadamia integrifolia*, *Mngnifera indica*, *Psidium guajava*, *Eriobotrye japonira*,*Musa sapientum* (Mithamo, *et. al.*, 2017). In Nigeria, coffee had been intercropped with both arable and trees crops like rice, cocoa, oil palm and kola, among others (Famaye, *et. al.*, 2020). This study made use of soil test and coffee leaf analysis evaluation to know the nutritional status of some old coffee plots both as sole coffee and as coffee/kola intercrop at both on-station and on-farm plots for appropriate soil nutrient management needs as veritable inputs for proper rehabilitation of Arabica coffee plantations at Kusuku,Mambilla Plateau, Nigeria.

MATERIALS AND METHODS

The field study was conducted at Kusuku using three coffee field locations A, B and C with location A being an on-station site in CRIN Kusuku Sub-station, cropped to sole coffee that has become very old and moribund, while location B was on-farm sole coffee plot site in Kusuku and location C was a coffee/kola intercropped plot. The studied plots were mapped out to contain 40 stands of coffee plants that were identified and leaf samples were collected for laboratory analysis. For the leaf sample collection, 4 coffee stands closed to the soil sample collection site were used. The 4^{th} leaf (indicator leaf) from the upper branches of the coffee plants was sampled. Soil samples at 0-30cm were also collected randomly at 10 different points per plot using soil auger. The soils collected per plot were mixed to form composite sample that represents each plot.

Collected soil samples were air dried in the laboratory, sieved through 2mm sieve and analysed using standard laboratory methods (AOAC, 1990) for the textural soil separates, pH, organic C, total N, available P, exchangeable cations which includes the K, Ca, Mg, Na and the exchangeable acidity (Al^{+3} + H^{+}). Soil particle size analysis was by hydrometer method (Bouyoucos, 1951), total nitrogen content was by Kjeldahl method (Bremner, 1996) and the pH was by pH meter in soil/water ratio of 1:1. Soil organic Cr was by Walkley – Black wet oxidation method (Nelson and Sommers, 1982). The soil available phosphorus was by Bray 1 method (Olsen and Summers, 1982), while the soil cation contents- Ca, Mg, K and Na were extracted with 1.0 M ammonium acetate (NH_4OAc) solution at pH 7.0. Exchangeable Ca and Mg in the leachate were determined by atomic absorption spectrophotometer (AAS) while the exchangeable K^{+} and Na^{+} was determined using flame photometer. The soil exchangeable acidity (Al^{+3} and H^{+}) was by leaching the soils with 1.0N KCl and titrated with 0.05N NaOH and HCl solutions (Mclean, 1982). The ECEC and base saturation levels were calculated. The soil micronutrients – Cu, Zn, Mn and Fe were determined after extracting the soils with 0.1N HCl and the filtrate was read using AAS (AOAC 1990). The micro-nutrient contents were determined and they include Mn, Fe, Cu and Zn.

The coffee and kola leaf samples were oven dried at 70 ^{O}C to constant weight, milled with stainless harmer mill and analysed for the N, P, K, C, Ca, Mg and Na contents in percentage, while the Mn, Fe, Cu and Zn contents were in mg/kg. The samples were digested using nitric-perchloric-sulphuric acid mixture (AOAC 1990) and N content was determined by micro-kjeldah approach while P was done by vandomolybdate colorimetry (IITA 1979) and K, Ca, Mg, Mn, Fe, Cu and Zn contents were read through AAS. The analytical results were compared with each crop corresponding soil and foliar nutrient critical needs (Egbe et. al., 1989; FAO, 2005).

RESULTS AND DISCUSSION

Soil textural properties

The soil separate analysis showed that the soils contained 638-688, 258-294 and 48-68 g/kg soil of sand, silt and clay respectively (Table 1). The soil separate distribution indicates that the soils were generally sandy loam in texture. The silt + clay contents ranged from 332-362 g/kg soil, which was higher than the critical level of 32 g/kg soil ideal for coffee and other tree crops cultivation (Egbe, *et al.*, 1989).This entails that the soils were able to hold sufficient water for the coffee plants, reduce seepage loss and guide against surface run-off that usually leads to soil structural damage (Palmer and Smith, 2013). Similar trend had been reported for soils under coffee cultivation in Uhonmora area of Edo State, Nigeria (Ipinmoroti and Ogeh, 2012)

Tables 1: Soil separate composition and textural class

Properties	On-Station plot	On-Farm Plot	kola/coffee plot
Sand (g/kg)	638	688	658
Silt (g/kg)	294	264	294
Clay (g/kg)	68	58	48
Texture	Sandy loam	Sandy loam	Sandy loam

Soil pH, Organic C and Nutrient Contents

The soil pH, organic C, macronutrients and ECEC contents (Table 2) indicates that the soil pH (4.44-5.90) were acidic. The on-station plot with pH of 4.44 was more acidic compared with the on-farm and coffee/kola intercropped plots. The on-station plot had history of repeated use of nitrogenious fertilizers hence the high acidic nature. However, the soil pH for both the on-farm and coffee/kola intercropped plots were within the soil pH range of 5.5-6.5 stated to be ideal for coffee cultivation, while it was below the critical for on-station plot. This calls for the use of liming materials on the on-station plot to checkmate the acidic condition of the soils, so that it will not become detrimental to coffee performance. Acidic soil condition had been reported to be of great influence on coffee production. A healthy coffee plant requires more than just nutrients; its acidity also needs to be at an optimal pH level, which is between 4.9 and 5.6, and between these levels, the plant is better able to absorb nutrients, resulting in more coffee cherries and less pest and disease-related issues (Cyamweshi, *et al.*, 2014).

The soil organic C for the on-farm and coffee/kola plots was 3.48 and 3.21% respectively, while it was 2.27% for the on-station plot. While the on-farm and coffee/kola plots had soil Organic C levels above the critical level of 3.0%., the on-station plot was below the critical level. The very low soil organic C of the on-station plot must have contributed to the very low pH level of the soil. The soil organic C must be improved upon through the use of organic fertilizers or judicious management of farm wastes and mulching materials on the plot. This act will help to correct the soils acidic nature on the on-station plot. This may be done along with the use of liming materials like dolomite. Organic manure usage had been reported to, among other benefits, helps to reduce soil acidity (Owaiye, 1993; Cyamweshi, *et al.*, 2014)

Table 2: Soil macronutrient contents across the coffee plots

Properties	On-Station plot	On-Farm Plot	Coffee/kola Plot
pH	4.44	5.50	5.90
N (g/kg)	1,45	1.86	2.13
Org. C (g/kg)	22.70	34.80	32.10
P (mg/kg)	27.09	20.84	18.97
K (cmol/kg)	0.32	0.58	0.41
Ca (cmol/kg)	1.86	6.06	7.48
Mg (cmol/kg)	0.60	0.85	1.15
Na (cmol/kg)	0.36	0.52	0.48
Al^{+3}+H^{+} (cmol/kg)	0.13	0.14	0.13
ECEC (cmol/kg)	3.17	8.13	9.62
BS (%)	95.99	98.34	98.63

The soil total N ranged from 1.45 – 2.13 g/kg soil, which was higher for the coffee/kola intercropped plot and it was least for the on-station plot. However, the amounts of N in the soils were higher than the critical level of 0.9 g/kg soil for coffee and 1.10g/kg for kola (Table 3). However, to maintain continuous coffee production on the plots at a sustainable level, it is advised that rational application of nitrogen supplying fertilizers based on yearly removal through crop harvest be made. This becomes imperative due to the very low contents of the soils organic C, which can result to sharp reduction in the soil nutrient supply and more importantly, N supply (Owaiye, 1993; Chatzistathis, *et. al.*, 2021). The soil available P ranged from 18.97 – 27.09 mg/kg soil. This range was higher than the soil critical level of 6.0 mg/kg soil for coffee. However, the value was least for the coffee/kola plot. This trend might be as a result of the additional demand and competition for nutrient by the kola plants in the intercrop. This suggests that a plantation of coffee/kola intercrop will need more attention in soil nutrient management in order to meet the needs of the component crops in the intercrop. This is because intercropping leads to competition for nutrients and may reduce coffee yields and quality (Mithamo, *et al.*, 2017).

Table 3: Coffee soil and foliar nutrient critical levels

Sample	N	P	K	Ca	Mg
	g/kg	mg/kg	←	cmol/kg	→
Soil	0.9	6.0	4.0	8.9	8.0
	←	%		→	
Foliar	1.10	0.07	1.40	0.37	0.13

The soil exchangeable cations indicated that K was 0.32 – 0.58cmol/kg soil. It was least for the on-station coffee plot (0.32cmol/kg) and highest for the on-farm coffee plot (0.58cmol/kg). The values were lower than the soil critical level of 4.0cmol/kg soil. The soil Ca content ranged from 1.86 – 7.48cmol/kg soil. The value was least (1.86cmol/kg) for the on-station plot and highest (7.48cmol/kg) for the coffee/kola plot. However, the Ca contents across the plots were lower when compared to the critical level of 8.9cmol/kg soil. The soil Mg content ranged from 0/503 – 1.151cmol/kg soil. The values were lower compared to the soil critical level of 8.0cmol/kg soil, which was in similar trend as obtained for the soil Ca and K contents. The soil Na content was 0.36 – 0.52cmol/kg soil. The values were low and could not pose any threat to coffee plants and the soil structure.

On the overall, the lower levels of the exchangeable cations compared to their critical levels indicated that there is need for appropriate fertilizer application for adequate supply of the nutrients for optimal and sustainable coffee berry yield on the plantations. This was in trend with the reports by Ipinmoroti and Ogeh (2014) when soils under coffee cultivation were evaluated in Uhonmora area of Edo State, Nigeria. The use of organic fertilizers or manures will be very appropriate so that the goal of improving the soil organic matter content could be achieved along with nutrients supply. Organic manures had been reported to meet the nutritional needs of tree crops like cocoa, kola, cashew and tea in Nigeria (Owaiye, 1993; Ipinmoroti, *et. al.*, 2008). The soil contents for Mg and K showed that the Mg/K ratios were 1.45, 1.57 and 2.48 for the on-station, on-farm and the coffee/kola intercropped plots respectively. It indicated that the coffee plots had inherent problem of nutrient imbalance supply, this is because the soil Mg/K ratio should be 2.0. Therefore, in the soil nutrient management activities, fertilizer application efforts should be geared towards correcting the Mg/k ratio imbalance, the coffee/kola intercrop seems to improve Mg/K ratio.

The soil exchangeable acidity (Al^{+3}+H^{+}) contents ranged from 0.127 – 0.135cmol/kg soil. This shows that the level of soil exchangeable acidity was very low compared to the exchangeable cations. This was reflected in the soil base saturation levels of 96.00 – 98.63% calculated for the soils. The soil effective cation exchange capacity (ECEC) ranged from 3.17 – 9.62cmol/kg soil. The value was least (3.17cmol/kg) for the on-station plot and highest (9.62cmol/kg) for the coffee/kola intercropped plot. The soil level of ECEC was considered to be too low when compared to 30cmol/kg soil that was ideal for soils suitable for the cultivation tree crops production on a sustainable level, with high quality produce (Solly, *et. al.*, 2020). The low ECEC level is of great concern since it is a useful indicator of soil fertility with ability to supply Ca, Mg and K. Inherently, the soils are very low in organic matter contents; this is coupled with the very low clay contents of 48-68g/kg soil (Table 1). These traits are characteristic of tropical soils of which Nigeria soils are inclusive (Igwe, 2011).

Micro-nutrients

The soil micro-nutrient contents (Table 4) showed that the soils Mn ranged from 14.45 – 48.05 mg/kg soil, while Fe content was 25.2 – 42.8 mg/kg soil, it was 3.295 – 5.15 mg/kg soil for Cu and 16.81–61.73 mg/kg soil for soil Zn content. Generally, the soil micro-nutrient levels were within the soil critical level sufficient for coffee production which forecloses the problem of micro-nutrients deficiency in the coffee plots. However, the use of fertilizer materials that could supply some quantity of the various micro-nutrients to the soils will be an added advantage in helping to replenish the soils of nutrients removed through berry harvest. This will help to maintain the soil nutritional level for healthy coffee productions (Abdulmumin, 2014). It helps in maintaining proper plant function and their deficiency can lead to variously physical symptoms in coffee plants.

Table 4: Plots soil micronutrient contents

Properties	On-Station plot	On-Farm Plot	kola/coffee plot
Mn	14.45	48.05	42.95
Fe	25.20	42.85	41.05
Cu	3.495	3.295	5.150
Zn	16.81	61.73	32.85

Coffee foliar nutrient contents

The coffee leaf N content ranged from 0.85 – 1.09% (Table 5) with the least value obtained for the on-station plot, and was highest for the on-farm plot. The values were however lower compared with the critical level of 1.10%. It was observed that despite the high soil N content, it does not reflect in the coffee plant. This might be as a result of N inhibitions in the soil (McCarty and Bremmer, 1989), this was in addition to the nutrient imbalance due to the Mg/K ratio. The leaf P content ranged from 0.04 – 0.11%. The on-farm and coffee/kola intercropped plots were higher in P contents than the critical while it was lower than critical for the on-station plot. This is a sign of P fixation in the soils of the on-station plot. This might be due to the very low organic C contents of the soil with resultant low organic matter and high acidic nature, with high tendency for P fixation (Mahdi, et. al., 2012).

The coffee leaf Ca contents (Table 5) showed Ca contents ranged from 0.61 - 0.74% with the on-station having the highest value of 0.74%, which was followed by the on-farm plot (0.64%) and it was least

(0.61%) for the coffee/kola intercropped plot. The coffee leaf Ca contents were higher than the critical value of 0.37% and were considered adequate for the coffee plants. On the other hand, the coffee leaf Mg content ranged from 0.10 – 0.12% which was low compared to the critical value of 0.13% and was not adequate for the coffee plants need across the various plots. Similar trend was obtained for the leaf K content with a ranged 019 – 0.52% which were lower than the critical level of 1.40%. This could have resulted from the Mg/K ratio imbalance in the soils. This trend is common in most tropical soils with continuous cropping without fertilizer usage and no soil evaluation practice to monitor soil conditions (Ipinmoroti and Ogeh, 2012).

The coffee leaf micro-nutrient contents showed that Mn, Fe, Cu and Zn ranged from 202 – 271, 905 – 952, 30.8 – 40.40 and 197.3 – 293.2 mg/kg soil respectively. These values were high when compared to the soil contents for the elements. It showed that crop removal was higher than their supply to the soil and this would not be able to maintain sustainable optimal quality coffee berry production on the plots. There is needed to make efforts at supplying the soils with adequate amounts. Hence, coffee produce from such plantations would not meet quality standard needed in the world market. This would eventually lead to low produce price at the world market (Agbonguironyi, *et. al.*, 2006; Abdulmumin, 2014).

Table 5: Coffee foliar nutrient contents across the plots

Nutrients	On-station Plot	On-farm plot	Coffee/kola plot
N (%)	0.89	1.09	1.07
P (%)	0.04	0.09	0.11
K (%)	0.19	0.41	0.52
Ca (%)	0.74	0.64	0.61
Mg (%)	0.11	0.12	0.10
Na (%)	0.33	0.31	0.29
Org. C (%)	17.83	22.57	20.41
C/N ratio	20.03	20.71	19.07
Mn (mg)	202.00	264.00	271.00
Fe (mg)	905.00	952.00	944.00
Cu (mg)	30.80	24.20	40.40
Zn (mg)	293.20	20.71	2 48.10

Nutrients needed based on deficiency levels

The overall data collected and analysed showed that there were significant variations in the soil organic C and nutrient contents of the various coffee plots (Tables 2 and 4). These suggested that the soil nutrient management needs would vary from one plot to the other, this calls for plot specific soil fertility managements of the coffee plots, for a sustainable coffee productions. The nutrient status of the various coffee plots showed that the on-farm coffee plot would need C, N, K, Ca and Mg applications while the other two coffee plots would need only the application of K, Ca and Mg. The on-station coffee plot would need 14.6 tonnes of organic manures while 20kg N ha^{1-} would be needed (Table 5). The coffee plots would need 6.24-7.36kg K, 2.84-14.08kg Ca and 13.7-14.8kg Mg ha^{-1} to meet the nutrient demand of coffee plants on the plots. From the Table, Mn, Fe, Cu and Zn supplying fertilizers would not be needed because the location soils are sufficient in these nutrients. However, for good soil health and quality coffee bean production, application of Mn, Fe, Cu and Zn should be based on their yearly removal through coffee berries harvests from the plantations.

The soil organic C need of 14.6 tonnes ha^{-1} was considered enormous that may difficult to cope with at ago (Farouque and Takeya, 2008), it could made a gradual process application of an average of 5.0 tons ha^{-1} year^{-1} until the soil organic C is sufficient for continuous and sustainable coffee production. This could be done through recycling of coffee wastes from the harvested berries, the use of other farm wastes like kola pod husks, cow-dungs, poultry droppings and market wastes that abounds in Nigeria (Adeoye, *et al*., 1993; 2005; Ipinmoroti, *et. al.*, 2007).

Nutrients	Plot Description		
	On-Station	On-Farm	Coffee/kola
Organic C (t/ha)	14.60	-	-
N (kg/ha)	20.00	-	-
K (kg/ha)	7.36	6.24	7.18
Ca (kg/ha)	14.08	5.68	2,84
Mg (kg/ha)	14.80	14.30	13.70

CONCLUSION

The study revealed the need for regular soil and plant nutrient content assessment in order to know the true condition of the coffee plantations and the need for appropriate ways to ameliorate the situation. The coffee plots were very low in the soil organic C, Ca, Mg and K contents. However, the short supply of N and P in the plant leaves requires that steps should be taken to reduce nutrient fixation in the soils. This could be achieved through appropriate organic fertilizer utilization to supply the nutrients and also helps to build up the soil organic matter and buffer capacity. Appropriate application of dolomites liming materials would help to correct the acidic condition as well as supply Mg in the soils to correct the imbalance in the soil Mg/K ratio.

ABSTRACT
The postharvest losses of horticultural products are very high and the rate of losses significantly depends on the type of products and postharvest handling practices. Effect of gum Arabic coatings combined with cinnamon oil on freshly harvested mature scotch bonnet fruits during storage was studied. The scotch bonnet was grouped into 3; Group A was the control and it was dipped in distilled water, group B was dipped in 10% gum Arabic + 3 ml of cinnamon oil and group C was dipped in 10% gum Arabic. The coated fruits were stored for 16 days and observed every 4 days for nutritional and physicochemical changes using standard methods. It was observed that Group C had the least incidence of decay and moisture loss at 40.80 % and 49.91 % respectively. Significantly ($p<0.05$) lower pH (5.98) and 0.56 % Total titratable (TTA) recorded for Group B revealed that the coating caused a reduction in the ripening rate of the fruit compared with the control (Group A) and Group C. Group B was effective in preserving the carotenoid contents of the stored fruits as it recorded the significantly highest values at day 16 for both Lycopene and β-carotene. Results from this study has revealed that 10 % Gum Arabic coating is an effective storage medium for scotch bonnet fruits, while the presence of Cinnamon essential oil helps to maintain the nutritional contents and as well slow down the ripening rate.
Keywords: *Postharvest, essential oil, horticultural, coating*

INTRODUCTION

On a global scale, postharvest losses of fresh produce are estimated to range from 15% to 50%. The main causes of this loss are microbial deterioration, a rapid rise in respiration, and the generation of ethylene, which causes fruit to ripen quickly even after harvest (Borah *et al*., 2016; FAO, 2019; Bist and Bist, 2021). In developing nations, where appropriate methods for storing fruits and vegetables are unavailable, this percentage is far higher (FAO, 2019). The principal causes of losses across the supply chain are postharvest pathogens and disease incidence, which are favored by these changes.Due to the non-degradability of synthetic coating materials, awareness is being drawn to use of eco-friendly biodegradable and bio-polymeric materials in preservation, of which Gum Arabic and essential oils are part.Essential oil, which is a natural compound extracted from aromatic plants. Most of these oils are generally recognized as safe (GRAS) for the environment and human health, and there is growing interest in using these oils for sustainable agriculture. A lot of research has been done with records to backup this claim that plant essential oils and extracts can serve as pharmaceuticals and food preservatives (Miguel *et al*., 2006).

In order to decrease these post-harvest losses, decay-control measures must be developed to retain the quality of fruits and vegetables and offer protection against post-harvest diseases.Thus, this study aims at development of an edible coating from natural bio-materials (gum Arabic and cinnamon oil) for postharvest management of scotch bonnet.

MATERIALS AND METHODS

Collection of materials

Cinnamon bark was procured from mandate market, Ilorin, Kwara State, while fresh Scotch Bonnet was obtained from a farm in Ilorin Kwara State and transported to Nigerian Stored Products Research Institute (NSPRI), Ilorin, Kwara State laboratory in reusable plastic crates in the early hours of the morning.

Extraction of cinnamon oil

Cinnamon oil was extracted as described by Abubakar *et al.* (2014)

Preparation and Application of coating medium

Gum Arabic coating was prepared according to the method of Utami*et al*., (2014) with modification. Ten gramme (10 g) Gum Arabic was dissolved in 100 mL distilled water at 50 °C on a hotplate and stirred for 60 minutes using a magnetic stirrer. The solution was filtered using a muslin cloth to eliminate impurities and 2 mL of glycerol was added as plasticizer to enhance the potency and elasticity of the solution. This was followed by the addition of 3 mL cinnamon oil and tagged solution A. Solution B was prepared as solution A above but without the addition of cinnamon essential oil. The Scotch Bonnet fruits were sorted washed and surface sterilized by immersing in 0.01% hypochlorite solution for one minute and air-dried. The fruits were divided into three (3) lots;Group A (control) was dipped in distilled water for 1-2 minutes,group B was dipped in solution A, and group C was dipped in solution Band allowed to air dry. The treated and untreated fruits were subjected to the same storage conditions and closely monitored with a data logger and stored for 16 days with chemical analysescarried out at 4 days interval.

Estimation of Decay Incidence (%) and Weight Loss (%)

The decay incidence and weight loss was calculated according to the procedure outlined by Lawal*et al*. (2019) and Fashanu*et al.* (2019) respectively.

Determination of Moisture content, Total Soluble Solid (TSS), pH and Total Titratable Acidity (TTA) (%)

Moisture content, pH, TTA and TSS of the stored fruits were determined according to the methods of AOAC (2019).

Carotenoids determination

Lycopene and β-Carotene contents were determined and calculated using the spectrophotometric method reported by Fashanu *et al*. (2019)

Determination of vitamin C content

Vitamin C content was determined using the 2, 6-dichlorophenol indophenol titrimetric method described by Lawal *et al*. (2019).

Statistical analyses

Triplicate data was subjected to Analysis of Variance (ANOVA) and tested for significant difference among treatments by New Duncan's Multiple Range F-Test (DMRT) at ($p<0.05$) using SPSS software package version 20.0.0

RESULTS AND DISCUSSIONS

Decay incidence and weight loss

Figure 1 shows the decay incidence and weight loss of the tested and control groups. Group C had the lowest decay incidence and weight loss at 40.80 and 49.91 % respectively after the experimental period. This group showed more pronounced effects in reducing the decay incidence and weight loss as compared with Group B, (treated with gum Arabic + cinnamon essential oil) and Group A (control). However the increased decay incidence recorded in group B could be as a result of reduced respiration rate caused by cinnamaldehyde; a major organic compound of cinnamon essential oil (Shen*et al*., 2021) thereby putting the fruits in a complete anaerobic state. This result is in agreement with the findings of Maqbool *et al*. (2011) where Gum Arabic and essential oil was used to prevent anthracnose in banana and papaya.

Total soluble solid (TSS)

The total soluble solids, ranged from 0.1 to 0.9 ºBrix (Fig. 2) with group A having significantly ($p<0.05$) higher value (0.9 ºBrix) compared to groups B and C at the end of the experimental period (Day 16).

Generally, there was an increase in total soluble solid as the storage days progressed, however there was no significant (p>0.05) difference between groups B and C at day 16. The increase in total soluble solid of both the treated and the control groups might be due to change in carbohydrate composition from starch to sugar as well as increased respiration rate which can be attributed to environmental conditions thus causing an acceleration to ripening of the fruits (Fashanu*et al.,* 2019).

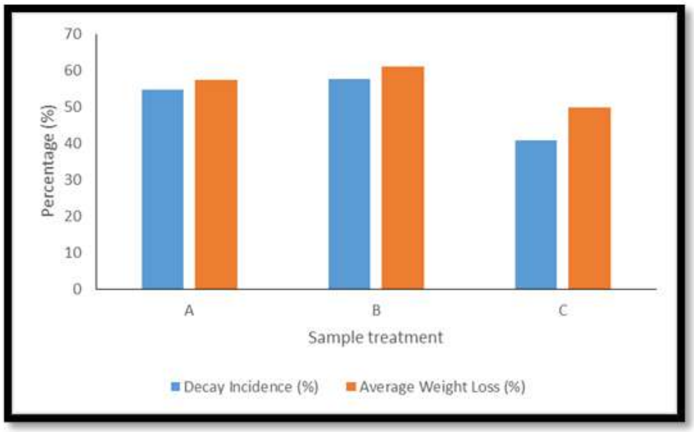

Figure 1: Effect of gum Arabic functionalized with cinnamon oil coating on Decay incidence and average weight loss of scotch bonnet. A=Control; B=10% Gum Arabic + 3mL cinnamon oil; C=10% Gum Arabic

pH and total titratable acidity (TTA)

The pH of both the control and tested groups ranged from 5.8 to 6.8 as shown in Figure 2. The control group had a significantly (p<0.05) higher value (6.8) at day 16 which was above the normal pH range of scotch bonnet (5.0-6.0) as reported by Bray, (2022). This result indicates that group B maintained the normal pH range of scotch bonnet and thus could be used in extending the shelf life of scotch bonnet. On the other hand, the TTA value recorded within the storage period ranged from 0.48– 0.95% (Table 1). There was no significant (p>0.05) difference in the TTA of control and treated samples at day 0, this was expected because they were all from the same source. Conversely, a significant (p<0.05) decrease was recorded for all Groups at day 16, with Group A and C showing no significant (p<0.05) difference. This showed that the acidity of the scotch bonnet reduced over the storage period. The results of pH and acidity are in agreement because, increase in fruit acidity correspond to decrease in pH. This result shows similar trend with the findingsof Maqbool*et al.* (2011)where Gum Arabic and essential oil was used to prevent anthracnose in banana and papaya.

Moisture Content (MC)

The moisture contents of the stored scotch bonnet fruits, as shown in Table 1, reduced as the storage days progressed and it ranged from 71.08to 88.07%. Group C had a significantly higher MC (79.98%) at the end of the experimental period. This showed that Gum Arabic alone is capable of reducing water loss during the storage period, which is in agreement with Ogungbemi *et al.*(2020).

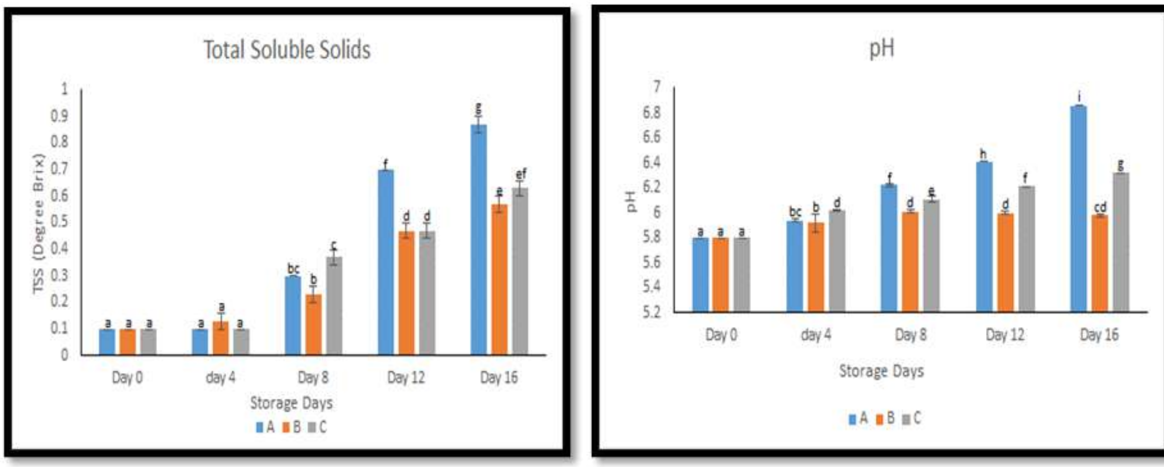

Figure 2: Effect of gum Arabic functionalized with cinnamon oil coating on total soluble solids and pH of scotch bonnet.

Each bar represents mean of triplicate readings (n=3). A=Control; B=10% Gum Arabic + 3 mL cinnamon oil; C=10% Gum Arabic. Bars with unshared alphabet are significantly different ($p<0.05$). Error bars represent standard error (SE) of the mean

Result shows mean ± SE of triplicate readings (n=3). A=Control; B=10% Gum Arabic and 3ml cinnamon oil; C=10% Gum Arabic. Bars with unshared alphabet are significantly different ($p<0.05$)

Lycopene, β-carotene and Vitamin C content

The lycopene contents range from 14.91 to 64.21µg/100g (Table 2) with group B having a significantly ($p<0.05$) higher value (64.2 µg/100g) while group C was significantly lowest (33.53 µg/100g) after the experimental period which lasted for 16 days. β-carotene content ranged from 14.34 to 36.77 with group B having a significantly ($p<0.05$) higher value (36.77 µg/100g) and group C (15.30 µg/100g). The Ascorbic acid content observed in Group C was significantly higher ($p<0.05$) than the other groups (28.27mg/100g) at day 16. The result from this study correlated with the studies of Guo *et al*. (2020) who noted that the incorporation of cinnamaldehyde with the carboxymethylcellulose based film packaging helps to maintain the storage quality of cherry tomatoes by suppressing some metabolic activities including respiration.

B	16	64.21i±0.07	$36.77^{h}\pm0.72$	$18.90^{c}\pm0.07$
C		$33.53^{f}\pm0.21$	$15.30^{a}\pm0.10$	$28.27^{g}\pm0.04$

Result showsmean±SE of triplicate readings (n=3). A=Control; B=10% Gum Arabic and 3mL cinnamon oil; C=10% Gum Arabic. Bars with unshared alphabet are significantly different ($p<0.05$)

CONCLUSION

The study has revealed that 10 % Gum Arabic coating is an effective storage medium for scotch bonnet fruits, while the presence of Cinnamon essential oil helps to maintain the nutritional contents and as well slow down the ripening rate.

INFLUENCE OF SOIL DEPTH ON JUICE VOLUME OF CITRUS FRUITS

Okafor B.N.
Citrus Research Programme, National Horticultural Research Institute, P.M.B 5432, Idi Ishin Ibadan.

Correspondence email: kpakpando2009@gmail.com

ABSTRACT
Citrus juice production is a prominent component of its productivity as it is one of the most utilized part of a citrus fruit. However, citrus juice volume and quality is affected by many factors including soil, agronomy and environmental factors. Juice volume assessment was conducted on Citrus Spp var Parson Brown cultivated on soils with degrees of shallowness (60cm, 90cm. >120cm). Matured Fresh citrus fruits were harvested and taken to the laboratory for juice volume assessment. Minimum juice volume varied from 50% (60cm depth) -52% (>120cm depth). Juice Mean values were 52.38%, 53.38% and 53.5% for tree growing on 60cm, 90cm and >120cm soil depths respectively. Highest volume was recorded in >120cm soil depth but this was not significantly different from 90cm depth although both soil depths were significantly different from 60cm soil depth. Soil factors can affect the volume of juice produced. Consequently, it is important to consider this; alongside other factors such as root stock and availability of moisture.
Keywords: *Citrus, fruits Juice volume, soil depth*

INTRODUCTION
Citrus juice contains 86-90% water. The quantity of water in citrus juice affects its acceptability in the market. Many factors affect the quality and quantity of citrus juice. These include soil, weather, rootstock and age of trees. Soil has always played an important role on human health and development. Post-harvest Reduction in juice water creates interesting opportune to remove moisture and making it store longer. Citrus fruit juice are highly nutritious and rich in Vitamins. Consequently, its production for juice need in Nigeria needs to be taken more seriously because of its export and nutritional values. The role of soil is of importance in considering citrus production because water and nutrient retention and absorption by plants are highly affected by soil properties. Shukla *et al.,* 2014 observed positive correlation between fruit parameters such as titrable acidity, total sugars, vitamin C, soluble solids concentration and available soil micro nutrients and macro properties. Environmental factors, moisture availability and absorption moisture have been reported as factors responsible for granulation in citrus. Subsoil constraints that can lower moisture availability in soils and its retention include presence of hard pans/impenetrable layers and high gravel content. Although citrus is a tree crop, over 60% of its roots are concentrated within 60cm of the root surface. This makes it very susceptible to drought and moisture stress; which will ultimately affect juice volume of fruits if it is not corrected by irrigation, This study was carried out to assess the percentage juice volume of *Citrus Sinensis var* Parson Brown as affected by soil depth due to presence of restrictive soil layers.

MATERIALS AND METHODS
Matured citrus fruits were harvested from 3 citrus orchards in NIHORT growing on soils with different levels of suitability due to presence of hard pans. Hard pans in the soils were observed at 60cm, 90cm and >120cm soil depth. Depths of restrictive layer were determined through auger borings in the orchards. Fruits harvested were labeled and taken to the laboratory for analysis. Fruits weight and juice volume were taken and percentage fruit juice was calculated as

$$Juice\ volume = \frac{Juice\ quantity}{Fruit weight} X\ 100.$$

RESULTS AND DISCUSSION

Table 1 shows the effective soil depth, minimum and maximum juice volume recorded per soil type. Highest juice volume was obtained in the soil with higher effective soil depth (>120cm).

Table 1: Descriptive statistics of juice based on soil depths

Soil types	ESD (cm)	Minimum Juice volume (%)	Maximum Juice volume (%)
A	60	50	53
B	90	51	56
C	120	52	55

NB: ESD = Effective Soil Depth

Nutrient and water absorbed by roots from soil are used for plant development. In the case of citrus, level of water absorption from the soils and extent of water availability affect the juiciness of citrus fruits. In citrus production, soil factors are issues to consider. Citrus responds significantly to drought in soils. This causes granulation and low juice quality. Soils vary in their properties and this also affects crop performance. Working on Mango in Brazil, Sequieira *et al* (2019) observed that soil K content and level of gravel contributed to the yield of Mango var Palmer. High gravel in soil affects citrus as gravel contents affect quantity of available soil water and further predisposes the soil to evaporation and low moisture content. According to Hartman (1981), high variability of tropical soils requires thorough studies for good management in order to attain sufficiency in food production. Spatial variability in soil properties results in unevenness in crop performance and makes modeling for soil management difficult (Doberman *et al.,* 1995; Lobell, 2004). Understanding soil variability offers a ley way to sustainable soil management as its response to treatment and use varies significantly with soil type (Jaradat, 2005). Citrus has a fibrous root system which decreases significantly below 60 cm depth. About 60 % of citrus roots reside within 0 – 50 cm, 30 % in 50 – 100 cm and 10 % in > 100 cm. Fibrous root system decreases significantly below 60 cm depth. Few roots are found at 120 cm soil depth (FAO, 2012; Paramasivum *et al.,* 2001; Alva, 2006). In cases where there is low utilization of irrigation, especially in the dry season, most citrus fruits shrivel and produce less juice. However, ability to tap into the water reservoir in lower soils depth can be used to advantage. This is more critical in the dry season and tree roots within the depth of available soil water tend to have more moisture than trees whose roots cannot reach the sub soils. This can reduce juice within fruits of harvested citrus. Juice volume recorded in the three soil types had significantly higher volume in soil types with higher effective soil depth compared to soils with lower soil type Table 2. Soil type A which has severe limitation due to rooting depth was highly marginally suitable for citrus production and was evident in the volume of juice produced by fruits grown on it.

Table 2: Variation in juice volume as affected by soil types

Soil types	Juice volume (%)
A	52.43b
B	53.39a
C	53.49a

CONCLUSION

Soil properties affect juice volume of citrus. It is important to ensure that citrus is cultivated in soils with little or no subsoil constraints such as gravel. Otherwise, adequate irrigation facilities should be put in place to unsure steady supply of water and forestall granulation of citrus fruits

PERCEPTION OF URBAN GREEN PARK IN IBADAN METROPOLIS OYO STATE

Ugege, B.H., Tunde-Francis, A.A., Kareem, A.T and Ogunsola, J.O
Federal College of Forestry, Ibadan, Oyo State, Nigeria

Corresponding author: Bukolasfavour@yahoo.com

ABSTRACT
The study examined the perception of urban green park in Ibadan metropolis Oyo state, Nigeria. Structured questionnaire were administered to eighty respondents. Descriptive statistics and logit regression were used to analyze the data. The result showed that nature friendly environment is one of the major factors that may influence the respondents visit to the park. The logit regression shows that age, gender, educational qualification, monthly income, marital status and awareness of the park variable were not statistically significant. Only the variable "Need for the park was statistically significant which means the odd that respondents will be willing to support conservation of the park. Based on the study it was observed that most of the respondents appreciate nature friendly environment and are willing to support conservation of the nature park.
Keywords: *Perception, urban, Green park, Ibadan*

INTRODUCTION

Green Park is a powerful tool in counteracting urban health dilemma. It is a land partly or completely covered with grass, trees, shrubs or other vegetation. Its presence in an area can serve a lot of benefit like providing recreational space for residents, improving physical activit, improve psychological well-being, enhance air and water quality, build climate resilience to flood risk and heat stress Its principally improves the quality of life of the citizen and contribute to the sustainable development of cities People who have more access to green environments tend to walk and be more physically active than those with limited access. Research has shown that when people are exposed to prolonged periods of excessive heat it creates health issues. This problem is made far worse when there is an absence of vegetation. In the face of expanding urbanization and urban population, which have adverse impact on environmental sustainability (Haq, 2011), green infrastructure is considered one of the best planning tools for adaptation to climate change (Yiannakou and Salata 2017). Studies have shown that lands with trees and vegetation produce more relaxed physiological states in people than lands that lack these natural structures, while supporting ecological constancy by providing habitats for wildlife, conserving soil, and enhancing biodiversity.

In Nigeria, urban green areas are scarce and well below the acceptable standards ($9m^2$ of green space per city dweller), as suggested by the World Health Organization (WHO, 2010). Despite all the apparent benefits of urban green space the development of a long-term planning strategy for urban green structure has never been a key priority for local (city and regional) policy makers. In light of the above, it is now predominantly essential to incorporate citizens' concerns, preferences and perceptions into the decision-making and planning processes regarding urban green infrastructure. The benefits derived from urban green area and their objective properties should be understood individually (Kothencz and Blaschke 2017). There is need to examine the perception of open green spaces.to encourage and promote green area.

METHODOLOGY

STUDY AREA

The study area is Agodi gardens and park. The garden is located in Ibadan North Local Government area. Agodi garden is situated near the Oyo state secretariat complex. It stands out as a green lung in the surrounding urban landscape with a great recreational potential. The garden was established as a biological and relaxation centre to provide recreational as well as educational services for inhabitant and visitor. In 1967 it lost it glory as a foremost centre particularly following its destruction by the famous 1980 flood disaster dubbed Omiyale that swept through the ancient city. The Agodi garden of Oyo state has been completely renovated to contain a zoo, swimming pool, bar and restaurants. It equally contains an indigenous forest, lake, tree plantation, and an abundant of medicinal plants and some rare tree species.

Table 1: Distribution of Demographic characteristic of respondent (visitors in the park)

Variable	frequency	percentage
Gender		
Male	37	47.4
Female	41	52.6
Total	78	100.0
Education status		
Secondary	8	10.25
HND/B.Sc	36	46.15
Postgraduate	34	43.59
Total	78	100.0
Marital status		
single	38	48.72
Married	40	51.28
Total	78	100.0
Occupation		
Government	19	24.42
Private organization	14	17.94
Self employed	14	17.94
Others (business)	31	39.80
Total	**78**	**100.0**
Household size		
1 - 3	17	21.79
4 – 6	44	56.41
7-12	12	15.39
Total	**78**	**100.0**
Age		
13-20	9	11.54
21-30	22	28.20
31-40	27	34.62
41-50	15	19.23
51-56	5	6.41
Total	**78**	**100.0**

Table 1 shows that most of the respondents are female (52.6%) this may be due to the fact that female like outing and excitement. This is in line with Ode Sang et al. (2016) who identified that women associate a greater sense of well-being with urban green area than men. In this sample size it was also observed that (40%) were married. High percentage of the respondent have formal education, (34%) have HND/B.Sc and (34%) have postgraduate degrees. This may be due to the fact that they are more enlightened about the need and benefit of recreation. (39.8%) of the visitors to the site are business men and women. This may be due to the nature of their job (not stereotype). It was also revealed that the middle age classes (31-50) have the highest visit to the park. this may be due to the fact that they are in their active age.

Table 3: Respondents perception on factors that influence visits to the park (park user)

Variable	Very well	%	Well	%	Don't know	%	Not at all	%
Proximity	23	(29.5)	26	(33.3)	10	(12.8)	6	(7.7)
Services rendered	20	(25.6)	36	(46.2)	10	(12.8)	2	(2.6)
Facilities in the site	26	(33.6)	31	(39.7)	5	(6.4)	8	(10.8)
Accessibility	29	(37.2)	34	(43.6)	4	(5.1)	1	(1.3)
Nature friendly environment	47	(60.3)	26	(33.3)	1	(1.3)	1	(1.3)
Cost of transportation Health benefit	17	(21.8)	35	(44.9)	8	(10.3)	6	(7.7)
Improvement in quality of air	27	(34.6)	23	(29.5}	15	(19.2)	2	(2.6)
Affordability	26	(33.3)	30	(38.5)	6	(7.7)	2	(2.2)
Learning and education	11	(14.1)	41	(52.6)	2	(2.6)	5	(6.4)
	16	(20.5)	32	(41.0)	9	(11.5)	4	(5.1)
Relaxation	41	(52.6)	32	(41.0)	4	(5.1)	1	(1.3)
Fun and entertainment	39	(50.0)	27	(34.6)	2	(2.6)	3	(3.8)

The result in table 3.0 revealed the perceived factors that influences visit to the park (that is those in the park during the administration of the questionnaire. (33.3%) consider proximity as one of the factors that influences their visit and 46% consider services rendered as one of the factors that influences their visits to the park, Also 39.7% sees facilities in the site as one of the factor that influences their visit), 43.6 % consider accessibility as one of the factor that influences their visit. Most of the respondents (60%) see nature friendly environment as a factor that influences visits to the park. 44.9% consider cost of transportation as one of the factor that influences their visit. 34.6% consider health benefit as one of the factor that influences their visit, 52.6% consider relaxation as one of the factor that influences their visit while 50.6% consider fun and entertainment as one of the factor that influences their visit to the park. From the table above it was observed that majority of the respondent appreciate green environment.

Factors determining respondents' willingness to support conservation

	B	S.E.	Wald	Df	Sig.	Exp(B)
Age	-.046	.062	.534	1	.465	.955
Gender	-.280	.740	.143	1	.705	.756
Education	.406	.513	.625	1	.429	1.500
Marital status	.170	.292	.339	1	.561	1.185
Monthly income	.000	.000	.939	1	.332	1.000
Park awareness	-18.636	2.838E4	.000	1	.999	.000
Need for park	2.886	1.319	4.789	1	.029	17.928
Constant	-.773	2.212	.122	1	.727	.461

From the logistic regression result, age, gender, educational qualification, monthly income, marital status and awareness of the park variables were not statistically significant. This implies that age, gender, education, marital status, monthly income and awareness of respondent of Agodi park do not have any meaningful influence on the decision of the respondents to support the conservation of the park. Only the variable "need for the park" was statistically significant. This means that the odds that respondents will be willing to support conservation of nature park in Ibadan based on their perceived need for the park is about 17.9 times more than those that will not be willing to support conservation of the nature park.

CONCLUSION AND RECOMMENDATION

The study has clearly shown that recreational park in Ibadan is highly esteemed with great multifarious potentials to meet both the social and economic needs of the teeming Ibadan metropolitan populace. Based on the result it is obvious that most of the respondents will be willing to support conservation of nature park in Ibadan based on the variable "need for the park" that is about 17.9times more than those that will not be willing to support conservation of the nature park. It is therefore recommended that Non-governmental Organization should be encourage to go into the establishment of more urban green recreational park, this will generate income as well as stimulate a clean and healthy environment.

ABSTRACT
Majority of the soils in Nigeria are exposed to leaching effects due to incessant rainfall that leads to low organic matter and nutrients contents. The importance of cocoa nutrition cannot be exaggerated because nutrition affects the size and cocoa bean quality. This study was carried out to review nutritional conditions and fertility status of soils for cocoa production in Nigeria. It was revealed that most soils under cocoa production in Nigeria are moderate to marginally suitable in fertility status. However, some of the soil contents for the nutrients needed for high cocoa yield were below critical levels. Therefore, good management practices that would replenish lost nutrient elements in the soil were considered necessary. Recommended rates of organic and inorganic fertilizers for cocoa cultivation are highlighted in this paper.
Keywords*: Nutrition, Soil fertility, Management, Cocoa, Nigeria.*

INTRODUCTION

Still called the "food of the gods", the cocoa tree (*Theobroma cacao* L.), of the Malvaceae family, is a tropical plant cultivated for its beans, from which cocoa powder and butter are extracted. There are three varieties of cocoa: "Forastero", usually yellow but occasionally red when the pod is ripe, "Criollo", more sought after and more expensive, whose pods are red-orange when mature, and "Trinitario", which is hybrid of the two preceding varieties. "Forastero" is the most commonly grown variety in West and Central Africa, but its flavour is not as good, as that of the other two varieties (Kokou Edoh Adabe and Lionelle Ngo-Samnick, 2014). Cocoa is a major source of income for about 5 million small-scale farmers (Poelmans and Swinnen 2016). Cocoa is produced within 10º N and 10º S of the equator where the climate is suitable for growing cocoa trees. West Africa has been the centre of cocoa cultivation for many decades, as two-thirds of the world's cocoa is produced in West Africa. Approximately 74% of the global production originates from four countries in West and Central Africa: Côte d'Ivoire, Ghana, Cameroon and Nigeria (ICCO 2020), where the cocoa plantations are among the least productive in the world (Oomes *et al.,* 2016). This is less than one-tenth of the potential yield of cocoa in West Africa (Zuidema *et al*., 2005).

A considerable part of the cocoa in the world is produced by smallholders, and the International Cocoa Organization (ICCO) estimates that approximately 14 million people are directly involved in cocoa production. Cocoa ranked first amongst agricultural export crops in its contribution to foreign earnings (Tijani *et al*. 2001). It is a crop of economic importance with more than 650,000 ha being cultivated in Nigeria (Sanusi and Oluyole 2005) Cocoa has generally enhanced the economy of Nigeria over the years. It is exported either as raw cocoa beans or cocoa products. Some 70% of Nigeria's annual cocoa exports are to Europe with a further 10% to the United States of America and up to 15% to Eastern Europe. Nigeria is currently the 4th largest producer of cocoa in the world. However, the gross production of cocoa has decreased since 2010 because of declining yields per hectare that started in the early 1990s (FAOSTAT, 2020). Because of the limited availability of land, productivity per hectare will need to increase if Nigeria is to contribute to the increasing global demand for cocoa.

In Nigeria, most of the Cocoa plantations are old and less productive (Ayoola 2000). Most soils under Cocoa plantations and adaptable areas in Nigeria are marginal to moderately suitable in fertility status. The soils are well drained, thoroughly leached and deeply weathered. Cocoa is exceptionally demanding in its soil requirement (Smith 1975). Wessel (1971) showed steady decline in almost all nutrients with length of cultivation. Omotoso (1975) reported that a crop of 1000 kg dry Cocoa beans removed about 20 kg N, 41 kg P and 10 kg K from the soil. It has been reported by Ogunlade *et al*. (2009) that most Nigerian Cocoa farmers don't use fertilizers on their farm. Soil fertility often deteriorates on cocoa farms (Adeniyi *et al*., 2017). Typically, cocoa trees planted on a freshly cleared forest initially benefit from high fertility due to high organic matter levels and well-developed soil structure. However, the subsequent removal of the harvested pods and beans can reduce nutrient levels (Boyer, 1973; Fassbender *et al.,* 1988; Hartemink, 2005; Thong & Ng, 1978; van Vliet *et al.,* 2015), and soil fertility declines if they are not replenished with organic or mineral/inorganic fertilizers (Aikpokpodion, 2010; Hartemink, 2005). Degradation can also occur due to the acidification of the soil from the use of acidifying fertilizers, like urea, organic matter decay, the removal and leaching of basic cations (Goulding, 2016), and an increased availability of toxic elements (Lal *et al*., 1989).

To maintain soil fertility, farmers typically apply amendments and fertilizers to replenish nutrients stocks and correct soil acidity. Few peer-reviewed studies have evaluated their effects both on cocoa productivity and soil properties, and where there is research, it often focuses on short-term effects on seedlings or young cocoa trees (Ahenkorah *et al.,* 1987; van Vliet *et al*., 2015; Wessel, 1971). Verlière (1981) reported that only a few fertilizer experiments with cocoa had provided significant results, and there was a need to determine the interactions between shade management, cocoa nutritional needs, and productivity. Low levels of adoption of good cocoa farming practices, pest and disease attacks, ageing plantations, and poor and decreasing soil fertility contribute to poor average yields (Wessel and Quist-Wessel 2015). Whereas reported yields at farm level vary from 300 400 kg ha^{-1} (Beg *et al*. 2017; Wessel and Quist-Wessel 2015) to 700–900 kg ha^{-1} (Jagoret *et al*. 2017; Jagoret *et al*. 2018), cocoa yields can reach >3000 kg ha^{-1} (van Vliet and Giller 2017; Yin 2004) in on-station trials. Crop simulation models suggest that the potential yield of cocoa exceeds 4000 kg ha^{-1} (Zuidema *et al*. 2005). Poor soil fertility is considered to be an important cause of the prevailing cocoa yield gap in Africa (van Vliet and Giller 2017). Soil fertility refers to the degree to which soils support plant growth. When forests are initially cleared for cocoa plantations, the soils are fertile and can sustain cocoa production for several years, referred to by Ruf and Zadi (1998) as the 'forest rent.' Continuous harvesting of cocoa with no additional fertilisers leads to a decline in soil fertility (Appiah *et al.* 2000; van Vliet and Giller 2017).

The decline of cocoa yields (WCF 2018) contributes to deforestation due to expansion of cocoa farming (Ruf and Zadi 1998). Maintenance and enhancement of soil fertility are essential to increase cocoa production with minimum negative environmental impact (Liniger *et al*. 2011; Vanlauwe *et al*. 2010; Vanlauwe *et al.* 2015). Several scholars cited by van Vliet and Giller (2017) have reported increased cocoa yields in response to fertilisation. For instance, in Ghana, the gross yield of fertilised plots was 61% to 116% higher compared with unfertilised plots (Appiah *et al*. 2000). During fertiliser experiments, yield response was stronger when cocoa was cultivated without shade (ibid.; van Vliet and Giller 2017). Besides mineral fertilisation, soil fertility enhancement can be achieved through the application of organic fertilisers or lime, and inclusion of legumes in the cropping system, or a combination of these (Hartemink 2006; MINADER 2018; Vos *et al*. 2003). The implementation of these practices requires farmers' recognition that declining soil fertility is a problem. Understanding the logic and rationale that underpin current farmers' management of soil fertility is essential for designing interventions to enhance yields. The paper reviewed nutritional conditions and fertility status of soils for cocoa production in Nigeria.

Soil and Land Requirements

Cocoa requires deep and well-drained soil for easy penetration of the roots. Poorly drained soil is inimical to this crop. It is predominantly grown on clay loam and sandy loam soils. It thrives well on wide range of soil types with pH ranging from 4.5-8 .0 with optimum being 6.5-7.0 (CPCRI, 2006). Soil nutrient content to achieve high productivity, cocoa requires a soil abundant in nutrients (Wessel 1971). The importance of other soil characteristics, such as pH, is largely due to their influence on the availability of nutrients. Cocoa needs a soil containing coarse particles and with a reasonable quantity of nutrients, to a depth of 1.5m to allow the development of a good root system. Below that level it is desirable not to have impermeable material, so that excess water can drain away. Cocoa will withstand waterlogging for short periods, but excess water should not linger. The cocoa tree is sensitive to a lack of water, so the soil must have both water retention properties and good drainage. The chemical properties of the topsoil are most important, as the plant has a large number of roots for absorbing nutrients. Cocoa can grow in soils with a pH in the range of 5.0-7.5. It can therefore cope with both acid and alkaline soil, but excessive acidity (pH 4.0 and below) or alkalinity (pH 8.0 and above) must be avoided. Cocoa is tolerant of acid soils, provided the nutrient content is high enough. The soil should also have a high content of organic matter: 3.5% in the top 15 centimetres of soil. Soils for cocoa must have certain anionic and cationic balances. Exchangeable bases in the soil should amount to at least 35% of the total cation exchange capacity (CEC), otherwise nutritional problems are likely. The optimum total nitrogen|total phosphorus ratio should be around 1.5 (International Cocoa Organization, 2020). In Nigeria, most of the Cocoa plantations are old and less productive (Ayoola 2000). Most soils under Cocoa plantations and adaptable areas in Nigeria are marginal to moderately suitable in fertility status. Cocoa can be grown in arecanut and coconut gardens as a mixed crop. It can also be planted in forest lands by thinning and regulating the shade suitably (Hamzat, 2005; Aroyeun, Olubamiwa, Adebowale, Adeogun and Ogunwolu, 2006).

Cocoa Nutrition

Cocoa plant requires adequate nutrients for optimum production. Both macro and micro nutrients are needed. Nitrogen (N), Phosphorus (P) and Potassium (K), Magnesium (Mg), Calcium (Ca), are required in large quantities while Zinc (Zn), Copper (Cu), Boron (B), Iron (Fe), Manganese (Mn), Molybdenum (Mo), Sulphur (S) and Chlorine (Cl) are required in small quantities. Quantities of these elements in the soil and plants are determined through soil and leaf sample analysis. Nutrients application is done to replenish those that are lost. Thus, fertilizers are needed to be applied in the necessary amount. UCDA, (2019) suggested that for proper and effective use of fertilizer, both soil and cocoa leaves should be sampled and analysed once in a year to determine the present status of nutrients and pH of such cocoa plantation. This would make for proper understanding of the nutrient recycling and management of fertilizer for optimum production of cocoa. Adejobi *et al.*, (2011) reported from a research carried out in Ibadan, Nigeria that the use of both chemical (NPK, Ca and Mg) and organic fertilizers significantly enhanced cocoa growth parameters, fresh, dry matter and dry cocoa bean yield.

The need to fertilize cacao (*Theobroma cacao* L.) emerged at the very beginning of the establishment of high-yielding commercial cacao plantations. Results of fertilizer trials were first published in a study conducted in Cameroon in 1910, quickly followed by Java, Trinidad and Ghana, among others (Verlière, 1981). The objective of these studies was to evaluate the effect of each nutrient supplied separately on cocoa yields. The results showed that phosphorus (P) and potassium (K) have always had positive effects on cacao yields. Although calcium (Ca) and magnesium (Mg) have also had positive effects on yields, the responses were much more variable and the quantities were dependent on the environmental condition. The variability of yield responses to nutrients pointed to the need to link the nutrients with each other or with other factors, in particular with soil, climate and topography. In the case of nitrogen (N), a significant effect on yields was rarely observed, except when the intensity of shading is reduced (Evans and Murray, 1953). There are three reasons for the contrasting effects of N (positive, neutral or negative) and its relationship to shading. First, due to the high vigor of the hybrid cacaos, the supply of nitrogen promotes vegetative growth at the expense of the production of pods (Alvim, 1977; Bastide *et al.*, 2003). Consequently, the positive effect of N on yields is only visible when the yield of pods is high and nutrient requirements are consequently high, which is more frequently the case when cacao is grown without shade.

Second, since cacao is cauliflorous, the fruits grow directly on the trunk and primary branches (at the base of the tree), while leaf production is concentrated in the apical branches (at the top of the tree). As N promotes vegetative growth, cacao uses the products of photosynthesis to produce more branches at the expense of flowering and fruiting. By increasing the amount of shade over the fruiting area, N can thus have a rather negative effect on production unless shading is controlled (Wessel, 1985).Third, when nitrogen deficiency occurs in the soil, the need for N may emerge and it becomes a limiting factor for other nutrients, which is quite a common phenomenon in soils with low organic matter content (Snoeck *et al.*, 2016). However, our study also showed that when cacao is grown under shade trees, recycling of organic matter increases soil N content, which improves soil quality with age, thus reducing the need for N in older plots. Nitrogen management should therefore aim for a balance between soil poverty and shade intensity. Based on the findings that P and K are always important and most often the only nutrients required, many governments recommend only one P–K–Ca–Mg-based fertilizer formula for their countries. The same formula may even be recommended in several other countries (e.g. Côte d'Ivoire, Ghana, Togo and Cameroon). Only a few countries (particularly, Brazil and Malaysia) have more specific recommendations, where fertilizer formulas are calculated based on critical N, P and K levels in the soil (Chepote *et al.,* 2013; Ling, 1984; Malavolta, 1997). This simplification, which consists in using very few formulations or even only one for a whole country, goes against the principle of nutrient management of the soil–plant system, which is based on two observations:

Each species has unique nutritional requirements and its own mechanisms underlying soil nutrient absorption. The specific nutrient requirements of cacao were deduced from the results of many trials conducted in many countries (Jadin and Snoeck, 1985).

• Each soil can only supply what it contains, and the availability of each nutrient in the soil varies with the type of soil in interaction and with the properties of the soil–root interface. In particular, pH may be a determining factor for P (retrograded forms) content and cations.

Thus, the objective of nutrition management is to correct the soil so that the cacao plant can find the nutrients it needs in optimal quantities and ratios. The fertilizer formula is determined by physical-chemical analyses of a sample of soil taken from each plot to be corrected. A plot corresponds to a map unit with the same soil and climatic conditions and homogeneous farming practices.

Fertilizer Management

Nigerian soils are generally low in quite a number of essential nutrients due to various factors such as erosion, leaching, bush burning, low activity clay, and among others, hence, these must be provided to foster good and optimum cocoa yield. Large quantities of human, agricultural, forestry and industrial wastes are produced annually which are not being effectively utilized. However, because of increasing costs of chemical fertilizers coupled with disposal problems posed by these wastes, their use as means of maintaining organic matter level and boosting agricultural productivity has become an economic proposition. Studies have shown that ash derived from wood, cocoa pod husk, saw dust, oil palm bunch and other plant sources increased availability of nutrients in the soil and crop respectively thereby causing a significant increase in yield of food crops such as vegetables, maize, yam, cassava e .t .c (Olomilua, *et al*., 2007; Ojeniyi *et al.*, 2007; 2010; Ezekiel *et al.,* 2009b and Ayeni *et al*., 2008a).

Akanbi *et al*., (2014) reported from there trail that Oil palm bunch ash (OPA) contained Ca, Mg and other essential micro nutrients in addition to N, P, K. Similarly, its addition enhanced cocoa seedling growth, dry matter accumulation and improved the soil nutrient status. Therefore, it could be recommended as soil amendment for a depleted soil.

Ogunlade *et al*. (2004) reported a superior performance of neem leaf, its availability all year round unlike the seasonal nature of neem seed production, neem leaf can be considered for organic fertilizer amendment towards the up-grading their N contents.

Ogunlade and Adeoye (2006) reported that the fortification of cocoa pod husk with neem is a release precursor for nitrogen and correction of soil acidification, which are critical factors in Soil fertility and plant nutrition evaluation in low acidity clay soils. They also report a higher soil pH of the amended soil which was probably due to supply of basic cations into the soil system by mineralization of the organic materials. Cocoa pod husk fortified or not fortified with neem seed or neem leaf and NPK gave similar values of height, number of leaves and stem diameter of cocoa seedlings. Fertilizer rates have significant effect on the growth and dry matter yield (DMY) of cocoa seedling. Both organic fertilizer and NPK applied at 10 kg N ha^{-1} significantly enhanced the height, number of leaves, stem diameter and dry matter of cocoa in Ibadan, South West Nigeria. Ipinmoroti *et al.* (2005) reported that manures were better nutrient sources than NPK fertilizers for cocoa seedlings, while formulated from urea + rock phosphate + mutilate of potash mixture was better than other NPK mixtures.

Available phosphorus in Nigeria cocoa soils is low and considered inadequate for good growth and production of cocoa, nutrient imbalance also exists. Low yield of cocoa in Nigeria can be attributed to soil fertility problems among others as clearly shown in an experiment carried out by Ogunlade and Aikpokpodion (2006). The main achievement of the third Nigerian breeding programme are the selection of 10 Nanay and 4 Parinary hybrids and the subsequent development and testing of the new CRIN varieties, all from among the Trinidad introduction population (Ojo and Sanwo, 1981). Amazon cultivars have been shown to respond very favourably to boron fertilizer and foliar applications, increasing the yield by about 30% (Ojeniyi, Egbe and Omotoso, 1981; Olaiya, 2005a). Ojeniyi (1981) reported a response to N (31-35 kg ha^{-1}) and P (36-207 kg ha^{-1}) in a N^4, P^2, K^2, B^2 fertilizer trial on 12-year Amazon cocoa. This result confirmed that phosphorus is the most limiting of all nutrient elements for cocoa production in Nigeria. The micronutrients requirements of cocoa have received considerable attention and of various micronutrients, boron, zinc and copper deficiencies have been found in both cocoa nurseries as well as in matured plantations (Olatoye, Egbe and Chude, 1987). Chude and Obigbesan (1983) detected that 5 ppm B applied, as solubor, was required to raise the leaf B level of six-month-old cocoa seedlings from deficiency to sufficiency level. Foliar application of boron was also recommended to reduce cherelle wilt in old cocoa plantation (Olaiya, 2005a).

Ogunlade *et al*. (2008) reported that the soil pH of their selected site (Ikoromaja cocoa farming community, Osun State was 5.8 fell within the ideal pH range of cocoa. While available P and exchangeable K, Ca and Mg were below the critical values of 10 mg kg ha^{-1}, 0.3, 5.0 and 0.9 cmol kg ha^{-1} soil respectively required by cocoa, the nitrogen, phosphorus and potassium contents of the organic materials indicated similar nitrogen content for both neem leaf and *Chromolena odorata*. All the fertilizers used in the experiment increased dry bean yield compared with control, pod yield was highest (though not significantly) under NPK fertilizer treatment probably due to higher rate of nutrient release compared to other fertilizers (cocoa pod husk based organic fertilizer and organ mineral fertilizer). In another study it was reported that cocoa pod husk compared favourably with the inorganic fertilizer (NPK) on growth parameter such as plant height at 3 and 4 months after transplanting (MAT). This could be an indication that cocoa pod husk could serve as an alternative nutrient source for cocoa seedlings.

Soils of moribund cocoa plantation or previously cropped lands with low soil available phosphorus 16 kg P (37 kgP_20_5) ha^{-1} could be applied. The use of Sokoto rock phosphate could be beneficial for longer period on the field for tree crops such as cocoa (Iloyanomon, 2008).

A trial was conducted at the experimental plot of cocoa research institute of Nigeria Ibadan to study the comparative effect of organically sourced cocoa pod husk ash (CPHA) and urea fertilizer application on soil properties and growth performance of cocoa seedlings in 2010 where the final results of the trial indicated that 25 t ha^{-1}, 30 t $ha^{-1}$and 20 t ha^{-1} of CPHA applications increased the soil, leaf N,P,K,Ca, Mg, Soil pH, organic matter and also plant height, stem diameter, number of leaves, leaf area, fresh and dry shoot weights of cocoa seedlings. It was concluded from the experiment that CPHA could serve as a good fertilizer and liming material for the cocoa seedlings (Adejobi *et al*., 2010).

Adejobi *et al.,* (2011) reported that the different combinations of organo-mineral fertilizer and cocoa pod husk ash are effective sources of organic matter, N, P, K, Mg and Ca for cocoa seedlings. Their application to soil increased growth or cocoa seedlings and uptake of nutrients. Cocoa pod husk can therefore be utilized to the maximum as organic fertilizer supplement and its combination with organo-mineral fertilizer enhance its performance to increase the growth of cocoa seedlings and nutrient uptake. Having reviewed the beneficial effects of applying the different sources of organic and inorganic fertilizers in the cultivation of cocoa in Nigeria. Agbeniyi *et al*., (2010) reported a Lacuna on the usage of fertilizers in cocoa production where they found out from there study that majority of cocoa farmers are not using fertilizer for cocoa production in the study area. They are doing this with the view that their soil is rich enough forgetting that there is a need to replenish the lost nutrients due to pod harvest from time to time.

CONCLUSION AND RECOMMENDATIONS

They study reviewed nutritional conditions and fertility status of soils for cocoa production in Nigeria. It was revealed that Nigerian soils are moderate to marginally suitable for cocoa production and will require good management practices to obtain optimum productivity. Therefore, deficient nutrients should be supplied through the use of appropriate organic and inorganic fertilizers which has been reported to increase cocoa productivity. In another twist, majority of cocoa farmers are not using fertilizer for cocoa production in Nigeria. They are doing this with a view that their soil is rich enough forgetting that there is a need to replenish the lost nutrients due to pod harvest from time to time. Due to this problem, the following recommendations were made:

a) Farmers should be trained on the relevance of soil test to know the fertility status of their cocoa farms. This is very important in view of the fact that some farmers were claiming that their farms were fertile enough and did not require fertilizers application.

b) Government and other stakeholders should encourage the production of cocoa pod husk fertilizer in as much that cocoa farmers are ready to use it to grow their crops. Apart from the fact that the fertilizer will boost cocoa production, it will also reduce the disease infestation that is likely to result due to compilation of cocoa pod husk constituting nuisance on farms.

c) Farmers should be encouraged to improve their level of education. This is quite imperative in as much that level of education was found to have affected the use of fertilizer for cocoa production. Illiterate farmers could be encouraged to undergo adult literacy programme.

ABSTRACT

Negative food safety reports over the use of synthetic pesticides in controlling bacteria disease of pepper caused by Xanthomonas campestris pv is increasing in Nigeria, hence the need for friendly options. This research sought to test the inhibitory potential of Achichi Seed Oil (ASO) extract at varying levels on bacteria spot diseases of pepper under field conditions with synthetic bactericide powder (Ridomil Gold) used as a positive control while distilled water constituted negative control. Result showed that application of ASO had bactericidal inhibition potential against the bacteria spot diseases comparable to the synthetic ridomil powder. Application of between 2 – 4 ml / 1liter of water of ASO was found to significantly influence the general performance of sprayed pepper in the study area. Further investigation should be carried out to determine the right volume between the ranges of 2 – 4ml of ASO that can effectively control the bacteria spot disease.

Keyword: *Achichi seed oil (ASO), bacteria spot disease, scotch pepper, inhibition potential, yield*

INTRODUCTION

Pepper cultivation in Nigeria has intensified in recent years with a total production of about 410,033 tons of pepper fruits for both processing and fresh market (Willis *et al.,* 2019) and for commercial and home consumption [Lengai *et al*., 2017; Tijjani et al., 2014]. It constitutes 7% of the total horticultural produce and 14% of the total vegetables grown in Nigeria [Willis *et al.,* 2019]. The fruit is always in high demand since it is consumed by nearly all the households. It is rich in capsaicin which is [Tijjani *et al.,* 2014] and also minerals and vitamins A, C, and E [Asante *et al*., 2013]. The largest percentage of peppers produced in Nigeria is under open field where they are vulnerable to diseases and pests [Wachira *et al.,* 2014]. Diseases such as bacteria leaf spot caused by *Xanthomonas campestris pv. vesicatoria* affect the quality, quantity, and profitability of pepper [Lengai *et al.,* 2017], more importantly when environmental conditions are conducive [Mizubuti *et al*., 2007] and losses can be close to 100% [Mugao et al., 2020]. The symptoms appear as spot lesions on leaves, stems and fruit, and occur on all stages of plant growth (Langston, 2009).

Farmers rely on synthetic fungicides in the control of disease on the field but, there are reported cases of toxicity and residue retention in the food products [Stangarlin *et al.,* 2011] and to beneficial and non-target pollinators [Naing *et al*., 2013] as a result of synthetic chemical misuse.

The worldwide trend to explore organic/biological pesticides as alternative options to synthetic ones is gaining popularity [Zaker, 2016] mainly because of its biodegradable, nonpoisonous, and safe to non-target pollinators and without harmful residues in the food products [Kimani, 2014]. Several plant compounds have been reported to control bacterial and fungal pathogens under vitro and in vivo domain [Nashwa, 2011]. The plant compounds contain essential oils (aromatic and volatile liquids) which have abundant bioactive compounds with antibacterial activity [Mugao *et al.,* 2020; Taghavi *et al,* 2018; Rasheed and Rasheed, 2017] that can replace toxic synthetic bactericide. The current study is therefore aimed at investigating the antimicrobial activity of varying levels of Achichi (*Canabis sativa* L.) seed oil (ASO) extract against pepper bacterial spot diseases under field conditions.

MATERIALS AND METHODS

Location of the study

The study was carried out at the Teaching and Research Horticultural Production Garden, Rufus Giwa Polytechnic, Owo, Ondo state, Latitude 7^0 12^N and Longitude 5^0 35^E, at 300m above sea level. Owo falls under guinea savannah transition zone with bimodal rainfall pattern which varies from 1200mm to 2000mm and spread from April to July, attaining the first peak in July and September to November with noticeable peak in September. The maximum and minimum temperatures of the area average are 29^0C and 15^0C and is also even throughout the year. The relative humidity is 60% during dry season but increase to 80% in rainy season

Collection of diseased pepper plant materials

Sampling was done in Horticultural Production Garden, Rufus Giwa Polytechnic, Owo. Pepper leaves with bacteria spot symptoms were randomly collected inside cool boxes by physical examination to the laboratory and refrigerated at 4^0C for processing and further analysis.

Isolation of the pathogens

V8 and Potato Dextrose Agar (PDA) (Naik *et al*., 2010) were the standard media used for isolation of *Xanthomonas campestris pv. vesicatoria* from the diseased pepper samples. The pepper leaves bearing bacteria spot symptoms were first washed under clean running tap water and then surface sterilized in 1% sodium hypochlorite for three minutes. They were rinsed in three changes of sterilized distilled water and blotted dry using sterilized blotting paper. A sterilized scalpel was used to cut infected leaf tissues of 3 × 3 mm size towards the healthy tissues where the pathogens were suspected to be more active.

The surface sterilized tissues were directly plated on the sterilized PDA and V8 agar for bacteria spot and then incubated in the laboratory at room temperature (27^0C) for three days. The colonies were then subjected to single spore isolation and sub-cultured on the media to obtain pure strains for identification. The isolates were identified using morphological microscopic and macroscopic features and comparing with established identification keys like gram stain, oxygen requirement, spore formation and shape. The isolates were then maintained on plates awaiting their inoculation on pepper plants in the field.

Extraction of achichi seed oils (ASO).

Clean seeds were poured inside a blender (industrial types XL Kenwood Chef Product) and were blended into powder. The powder was then poured inside a rubber container filled with hexane and allowed to stay for 36 hours, so as to get the desired liquid. The achichi seed powder and hexane were poured into a muslin cloth and squeezed with hand to get the extraction of achihi oil needed and the remaining residue left inside the muslin cloth was dispose. The liquid was allowed to settle for 22 hours and then separated. Retort stand was use to hold the soxhlet, condenser was connected to the soxhlet to cover it, boiling flask was connected to the soxhlet to cover it, mantle machine was plugged for heating. The achichi oil was poured inside the boiling flask and put on top of the mantle machine for boiling. It was made to boil for 25 minutes while connected to run through condenser with running water for cooling the hexane pressure. The soxhlet annexed the drops of hexane from the condenser and the extracted achichi oil remains in the boiling flask. The oil was later poured inside a beaker, put inside the oven for 45 minutes in order to drain out remnants of hexane inside the extract. The oil was later bottled and stored in the refrigerator till application in the experiment.

Experimental Design and Layout

The experiment was laid out in a Randomized Complete Block Design (RCBD) with four treatments replicated four times. There were six main plots in a block representing the plants inoculated by the pathogens (*Xanthomonas campestris pv*. vesicatoria). The three treatments comprised ‘control, achichi seed oils at 2 and 4 ml concentration, the positive control (Ridomil Gold synthetic fungicide), and the negative control (distilled water). Ridomil Gold is a curative fungicide manufactured by Syngenta (https://www.syngenta.co.ke/ product/crop-protection/ridomil-gold-mz-68-wg) and comprises Metalaxyl-

M 40 g/Kg and Mancozeb 640 g/Kg formulated as wettable granules. The test pepper variety was Scotch bunnet pepper (Rodo) bought from local market in Owo. It was not specified as being resistant to bacteria spot of pepper.

Prior to planting, the land was tilled, using hand hoe and well decomposed manure was worked into the soil. The land was irrigated to improve the moisture status of the soil. One-month-old pepper seedlings were transplanted in the field

Preparation of Inoculum

Fourteen-day-old cultures of Bacteria spot disease was used as source of the spores. Spore suspension was prepared by adding 5 ml of sterile distilled water to a pure 14-day-old culture in a Petri dish. Dislodging of spores was done with a glass rod and the content sieved using a three-layer cheese cloth to remove the mycelia. The hemocytometer slide was used under a microscope to ascertain the spore suspension concentration and then standardized to 1 × 106 spores per millimeter with sterile water. The inoculum was stored in the refrigerator, at 4^0C, awaiting inoculation.

Inoculation and application of treatments

Inoculation was done on actively growing pepper plants two weeks after transplanting by spraying every plant with the 20 ml of the inoculum using a hand sprayer. Symptoms of disease development began to appear on the 7th day after inoculation. In the preparation for spraying, 2 and 4 ml of achichi seed oil were first mixed separately with sterile distilled water to up to 500 ml thoroughly. Ridomil Gold solution was prepared following the manufacturer's instructions of 2.5 g per liter of water.

Subsequent applications were done after every ten days up to harvesting stage of pepper fruits.

Data Collection and Analysis

Disease severity was scored per treatment after every ten days using a 0–5 scale [Latha *et al.,* 2009] based on the size and number of lesions on the infected leaves as follows:

(i) 0 = healthy (no visible lesions on the leaf)

(ii) 1 = up to 10% of the infected leaf area

(iii) 2 =11%–25% of the infected leaf area

(iv) 3 = 26–50% of the infected leaf area

(v) 4 = 51–75% of the infected leaf area

(vi) 5 = more than 75% of the infected leaf area

The disease scales were converted into percentage for each plant using the formula described by Chaerani and Voorrips (2006) as provided in the equation.

$$\text{Disease severity} = \frac{\text{Sum of all ratings} \times 100}{\text{No. of leaves sampled} \times \text{maximum disease scale}}$$

The disease severity on each plant was determined according to the average of all leaves of a plant counted based on visual assessment [Derbalah *et al*., 2011].

Data was also collected on growth and yield parameters including plant height, number of branches / plant, number of leaf / plant, days to 50% flowering, and number and weight of marketable fruits.

All the data was subjected to Analysis of Variance (ANOVA) using SPSS version 2019 and separation of means was done, using LSD (Least Significant Difference) at 95% level of confidence.

RESULTS AND DISCUSSION

Severity of bacteria spot disease on inoculated pepper plant

Severity of bacteria spot disease on pepper plants inoculated with *Xanthomonas campestris* kept increasing throughout the period of experiment (Table 1). At 2 WAT, the severity of the disease reduced significantly (p > 0.05) with application of achichi seed oil. The achichi seed oils at 4 ml concentration gave similar results to the synthetic fungicide (Ridomil Gold®) used as positive control. The two concentrations (2 ml and 4 ml) varied significantly with the negative control (distilled water). For both concentrations, disease severity was significantly reduced. At low concentration of achichi seed oil (2 ml.) resumption of inhibition commenced late, while the severity continued to increase in negative control treatment.

Effects of achichi seed oils on number of leaf, plant height, and number of branches of pepper inoculated with bacteria spot disease at 2,4,6,8 and 10 WAT

Result showed that there was no significant ($p > 0.05$) difference across all treatments in number of leaf at 2 and 4 WAT. At 6, 8 and 10 WAT, significant difference ($p < 0.05$) were observed under different treatment levels. Control treatment recorded least number of leaves while positive control and two levels of achichi seed oil treatments recorded significantly high values. There was no significant difference in number of leaf at positive control and the two levels of ASO at 6, 8 and 10 WAT. Achichi seed oil at 4 ml (19.58) > 2 ml (18.15) > Ridomil gold (18.11) and > control (12.58) (Table 2).

The pepper plants inoculated with bacteria spot disease did not show significantly variation in height across all treatments at 2 WAT. At 4 WAT the pepper plants under control treatment showed significantly ($p < 0.05$) low plant height (3.41 cm) than all the other treatments. Positive control, 4 ml and 2 ml of achichi oil treatments did not show significant variation in plant height. At 6 WAT the plant height varied significantly ($p < 0.05$) among the treatments with plants in the control treatment being shortest in relation to the plants treated with 4 ml, 2 ml and Ridomil gold (control). Pepper plants sprayed with 2 ml achichi seed oil and positive control (Rindomil g) did not vary significantly in plant height, but 4 ml was significantly higher from both the positive control and 2 ml treatments (Table 3).

There was significant influence of treatments on bacteria spot disease on number of branches of pepper plant across all stages of measurement ($p < 0.05$). Among treatments, the negative control recorded the lowest number of branches while pepper plants sprayed with 4 ml of achichi seed oil showed increased number of branches. There was no significant difference in number of branches on plants treated with 2 ml of achichi seed oil and positive control treatments (Table 4).

Effects of achichi seed oils on days to 50% flowering of pepper inoculated with bacteria spot disease

The treatments significantly ($p < 0.05$) influenced the number of days to 50% flowering on the pepper inoculated with bacteria spot disease. Treatment at 4 ml of achichi seed oil had significantly shorter days to attain 50% flowering date followed by the positive control, then 2 ml. The negative control treatments took longest time to attain 50% flowering date in relation to the other treatments (table 4).

Effects of achichi seed oil on number of fruit and fruit weight per plant of pepper inoculated with bacteria spot disease.

The number of pepper fruits produced varied significantly ($p < 0.05$) among the treatments (Table 4). Among pepper plants inoculated with bacteria spot disease the negative control recorded the lowest number of fruits per plant. The number of fruits per plant increased with application of positive control (Rindomin G =5.88) and achichi seed oil extracts (4 ml =5.99) and (2 ml =5.86). there was no significant ($p > 0.05$) difference among treatments. Also**,** application of achichi seed oil at 2, 4ml and positive control (ridomil gold) on pepper plants significantly influenced fruit weight of pepper than the negative control. Application of achichi seed oil at 4 ml increased fruit weight more significantly than positive control (Ridomil Gold) and 2 ml. Values of positive control and 2 ml were not significantly ($p > 0.05$) different levels (Table 4).

Table 1: Effect of achichi seed oil on disease severity of inoculated pepper plant

NOTE: ** = very significant, * = significant, ASO = Achichi Seed Oil, DTO =Days to Flowering, LSD = Least Significant Difference, WAT= Week After Transplanting.

DISCUSSION

Disease severity was not significant on the number of leaf at 2 – 4 WAT. The reason could be attributed to inherent genetic resistant of the pepper plant against the disease during the formative stage of the pathogen and also that the environment may not compromise with quick establishment of the pathogen at the time of inoculation (Chatfield, 2000). At 6 – 10 WAT disease severity was high on pepper plants inoculated with bacteria spot under negative control, reducing the plant vegetative growth (number of leaf, plant height and number of branches). Pepper plants inoculated with bacteria spot under positive control (Rindomil gold) and the two levels of achichi seed oil (2 and 4 ml) had low severity of disease infection, hence increase vegetative growth (number of leaf, plant height and number of branches), showing that the disease suppression mechanism, though varied with application level of the treatments, were effective. Kagale *et al*., (2004) pointed out that the mechanism of diseases suppression may be either by active antimicrobial compounds acting on the pathogen directly by destroying their membranes thus lowering disease development. This study showed that the antibacterial effects of achichi seed oil (ASO) reduced the chance of the pathogen developing resistant traces after application (Rasheed and Rasheed, 2017) and was comparable to that of Ridomil Gold synthetic fungicide (Lengai *et al*., 2017; Nashwa and Abo-Elyousr, 2012).

Flowering accounted for fruiting and yield of crops. This study showed that ASO efficacy was reflected in the attainment of Days to 50% flowering stage, fruit and yield of pepper when compared with the untreated control. Late resumption of days to 50% flowering stage of pepper plant under negative control was indication that the pathogen had implicated the physiological and biological processes of growth of the plant thereby affecting flowering formation. On the other hand, plants under positive control (Rindomil gold) and the two levels of ASO assumed 50% flowering stage early which led to production of more flowers that eventually increased fruits and yield of pepper, which showed the capacity of ASO in controlling bacteria spot disease of pepper. Essential oil, according to Din *et al*., [2016], contains secondary metabolites such as organosulfur, phenols, and alkaloids which are antimicrobial which reduce the chance of pathogens to cause disease in plant. This corroborated the theory of Naing *et al*. [2013] that some organic pesticides induce disease resistance systems of the plant which lead to healthy growth of the plants and thus better production. Nashwa and Abo-Elyousr, [2012]; Ahmad *et al*., [2017] also showed that the Eucalyptus camaldulensis (eucalyptus), Ocimum basilicum (sweat basil), Allium sativum (garlic), Nerium oleander (oleander), Datura stramonium (jimsonweed), and *Azadirachta indica* (neem) plant extracts boosted the yield of tomato as compared to the control.

CONCLUSION

The study showed that the essential oils from Achichi seed (*Canabis sativum* L. seed) is as effective as the Ridomil Gold ® synthetic fungicide in managing the bacteria spot of pepper. The treatments significantly boosted the growth and yields of pepper plants. The essential oil can therefore be incorporated in the bacteria spot management as eco-friendly option to synthetic pesticides. This will lower the chemical residue levels in fruits of pepper thus improving the fruit quality and reducing the risks and hazards of toxic fungicides.

RECOMMENDATION

Further research should be conducted to determine the right volume between 2 – 4ml of ASO (achichi seed oil) extract that will effectively control or inhibit the severity of bacteria spot disease on pepper that will not lead to waste of material and resources.

ABSTRACT

The prevalence of micronutrients deficiency especially vitamin A is on the increase due to poor dietary intake. Hence, there is need to address this problem with pro-vitamin rich foods. Pumpkin which has high carotenoid content is a good candidate for alleviating vitamin A deficiency. The effects of boiling and steaming on the carotenoid contents in the pulp of two pumpkin varieties (Orangetti and Connecticut field) obtained from National Horticultural Research Institute farm around July 2023 was modeled and optimized. The pumpkin pulp was steamed and boiled for varying time between 0 to 6 minutes, and total carotenoid content was determined on it. The result showed that the carotenoid content decreased for variety 1 (Orangetti) after treatment from 13.79 to 9.40 µg/g. while the second variety increased after treatment from 8.96 to 29.40 µg/g. Central composite design of response surface methodology was used as statistical indicator with boiling and steaming time (0-6 minutes) serving as independent variables. As indicated by p-values that of 0.01 and 0.02, both boiling and variety had a significant impact on the carotenoid content of pumpkin pulp. However, steaming had no significant impact on the carotenoid content. The optimization result revealed that Connecticut field was the most desirable with 28.511 % of carotenoid by steaming at 2.6 minutes and boiling for 6 minutes. This study deduced that application of heat to pumpkin improved the carotenoid content compared to the raw form.

INTRODUCTION

Micronutrients malnutrition, particularly vitamin A deficiency, affects about three billion people worldwide (Pritwani and Mathur, 2017). Vitamin A Deficiency (VAD) has afflicted around 5.2 million preschool-aged children and 9.8 million pregnant women, primarily in sub-Saharan Africa , according to the World Health Organization (WHO) (Ohanenye *et al.*, 2021). Vitamin A is required for adequate vision, epithelial tissue integrity, and a wide range of other metabolic processes (Pritwani and Mathur, 2017). According to studies from developing countries, pro-vitamin A-rich foods account for up to 80% of dietary vitamin A intake (Cardoso *et al.* (2009);Van den Berg *et al.* (2000). Vitamin A is available in the form of pro-vitamin A carotenoids, which are pigments generated by many plants and found in green, orange, and yellow plant tissues. Most fruits and vegetables contain carotenoids and encouraging their injection daily can serve as a good potential in tackling VAD. According to the report of Pritwani and Mathur (2017), vegetables that are excellent sources of carotenoids include but not limited to carrots, green pepper, spinach, sweet potato, and pumpkin.

Pumpkin also referred to as squash exist in the family of Cucurbitaceae, genus Cucurbita (Shamsuri and Ahmad, 2019). It is widely grown throughout the tropical and subtropical countries. The most common species of pumpkin are C. maxima, C. pepo, and C. moschata (Lucia Maria Jaeger *et al.*, 2012). The flesh of the fruit is distinguished by its hard outer cover with characteristic yellow to orange colour which indicates the presence of carotenoids, with firm texture and flavour (Chuwa *et al.*, 2022). Rodriguez *et al.*

(2018) reported that the fruit is abundant in minerals such as potassium, calcium, phosphorus, ß-carotene (which can be converted to vitamin A), dietary fibre, and lycopene. Vegetables are eaten in either raw or cooked form. Research has shown that most nutrients in fresh vegetables are preserved in the raw condition, however any degree of cooking leads in partial loss of nutrients and significant changes in its sensory properties. Some researchers have conducted studies on the effects of different cooking methods on pumpkin (Shamsuri and Ahmad (2019);Lotfy *et al.* (2017). However, studies focused on modeling and optimization of cooking methods on the total carotenoid content of pumpkin is very hard to come by. Therefore, this study modeled and optimized the effects of boiling and steaming on the total carotenoid content of two varieties of pumpkin using response surface methodology (RSM).

Variety 1 (Orangetti)

Variety 2 (Connecticut field)

MATERIALS AND METHODS

Sample preparation

Two pumpkin varieties (Orangetii and Connecticut field) cultivated and harvested at the same time were obtained from the Research Farm of National Horticultural Research Institute, Ibadan, Oyo State. Fresh samples were washed and peeled to remove the outer skin. The seeds were removed and the pulp was cut into smaller sizes and divided into eight portions to increase the surface area in order to facilitate the treatment process i.e. boiling and steaming. For boiling, 20 g of the sample was randomly selected from the lot and was immersed in boiling water at 100°C for 0 to 6 minutes based on the experimental design while steaming was conducted by placing 20 g of the sample above boiling water in a steamer with lid for varying time between 0 to 6 minutes.

Determination of total carotenoid

The total carotenoid content of the pumpkin was determined according to the method oLucia Maria Jaeger *et al.* (2012) with little modification. This was done by weighing 0.5 g of the mashed sample into a 20 ml test tube and 5 ml of cold acetone was added and mixed to form a paste, and the mixture was continuously shaken until it became colourless. The extract was then transferred into a 100 ml separating funnel containing 8 ml of n-hexane, and the acetone was separated by slowly adding water to avoid the development of an emulsion, and the aqueous phase was discarded. The technique was repeated until there was no more remaining solvent. The procedure was repeated until no residual solvent remained. Then the extract was transferred to a 50 ml volumetric flask containing 3 g of anhydrous sodium sulfate and the volume was made up to its full volume by adding n-hexane and read at 450 nm with a UV-visible spectrophotometer (T80 series UV-visible double beam spectrophotometer).

$$\text{Carotenoid content } (\mu g/g) = \frac{A \times V(ml) \times 10^4}{A^{\%}\ 1cm \times P}$$

Where A= Absorbance; V=Total extract volume; P= sample weight; $A^{\%}{}_{1cm}$ =2560 (ß-carotene Extinction Coefficient in n-hexane).

Experimental design and statistical analysis

The experimental design used in this study was the central composite design of response surface methodology; with three independent variables; in which two are numeric (boiling (0-6 minutes) and steaming (0-6 minutes), and one categorical factor (varieties). A total of 18 experimental runs was generated using Windows design expert version 13. Table 1 below gives the details of the experimental runs and the treatment combinations considered for each of the run. The data obtained for the corresponding carotenoid content responses for each of the runs was then subjected to multiple regression analysis. This was done by fitting the data into polynomial models whose fitness was verified using R^2 (coefficient of determination) and the corresponding p-value.

RESULTS AND DISCUSSION

The carotenoid content of the pumpkin pulp decreased after steaming and boiling for Orangetti from 13.79 % to 9.40%. While for Connecticut field, the carotenoid content increased upon steaming and boiling from 8.96 % to 29.40% as shown in table 1 below.

Table 1: Experimental runs, treatment combinations, and carotenoid content of the two varieties of pumpkin pulp.

Runs Variety 1	Factor 1 A: Steaming (minutes)	Factor 2 B: Boiling (minutes)	Carotenoid content (µg/g) Mean ±S.D	Runs Variety 2	Factor 1 A: Steaming (minutes)	Factor 2 B: Boiling (minutes)	Carotenoid content (µg/g) Mean ±S.D
1	0	0	**13.79**±0.51	**10**	0	0	8.79±0.16
2	6	0	**10.38**±0.92	**11**	6	0	21.29±0.10
3	0	6	**8.92**±0.75	**12**	0	6	24.06±0.13
4	6	6	**12.86**±0.80	**13**	6	6	22.34±0.13
5	0	3	**10.00**±0.47	**14**	0	3	17.17±0.57
6	6	3	**11.46**±0.67	**15**	6	3	19.25±0.06
7	3	0	**7.94**±0.13	**16**	3	0	8.96±0.24
8	3	6	**10.60**±0.82	**17**	3	6	29.40±0.41
9	3	3	**9.40**±0.35	**18**	3	3	20.23±0.25

As shown in the table below, the p-value of the model is 0.0215 which is less than 0.005, indicating that the model is significant. Due to the p-values above 0.05, steaming (A) is not a significant factor while boiling (B) and variety (C) is a significant factor. However, the interaction between AB and AC are not significant, while BC and ABC are significant. This implies that both boiling and variety affects the carotenoid content no matter the treatment time of exposure while steaming does not influence the carotenoid content. The model's F-value of 5.76 obtained implies that the model is significant, and it is a good fit for predicting the responses. An R^2 value of 0.91 indicates that the model is a good predictor for the data.

Table 2: Analysis of variance table for carotenoid responses.

Source	F-value	p-value
Model	5.76	0.0215
A-Steaming	1.79	0.2292
B-Boiling	11.16	0.0156
C-Variety	9.42	0.0220
AB	0.5769	0.4763
AC	0.9630	0.3643
BC	10.83	0.0166
ABC	5.69	0.0544

Model equation for carotenoid content of the pumpkin

$12.85130-1.78426S-0.905741B+0.204259SB+0.213580S^2+0.051358B^2$ …….Equation 1

$7.07889+2.37426S+3.05500B-0.395185SB-0.079074S^2+0.028704B^2$ ……......Equation 2

The model equation above can be used to predict the value of carotenoid content in the pumpkin as steaming and boiling time varies.

The Figure 1 below shows the interaction of steaming (A) and boiling (B) time with the varieties on the carotenoid content of pumpkin respectively. The two undotted lines denotes the first (Orangetti) and second variety (Connecticut field) respectively. It can be observed that for the first variety (Orangetti), between 0-6 minutes the carotenoid content is constant and falls around 10 for both steaming and boiling i.e., the carotenoid content remains constant between that time range. While for the second variety (Connecticut field), the carotenoid content shows an increasing trend for steaming and boiling from 0-6 minutes. Though, boiling exhibited a more increasing trend than steaming. It can also be observed that the second variety has better carotenoid content than the first variety. According to Hwang *et al.* (2012), thermal treatment improves carotenoid availability. Similar findings were reported by Shamsuri and Ahmad (2019). Cooking methods degrade food matrices and loosen carotene-binding fibers. This may result in nutritional loss, but it may also improve bioavailability and enhance carotene content (Fernández-García *et al.*, 2012).

A B

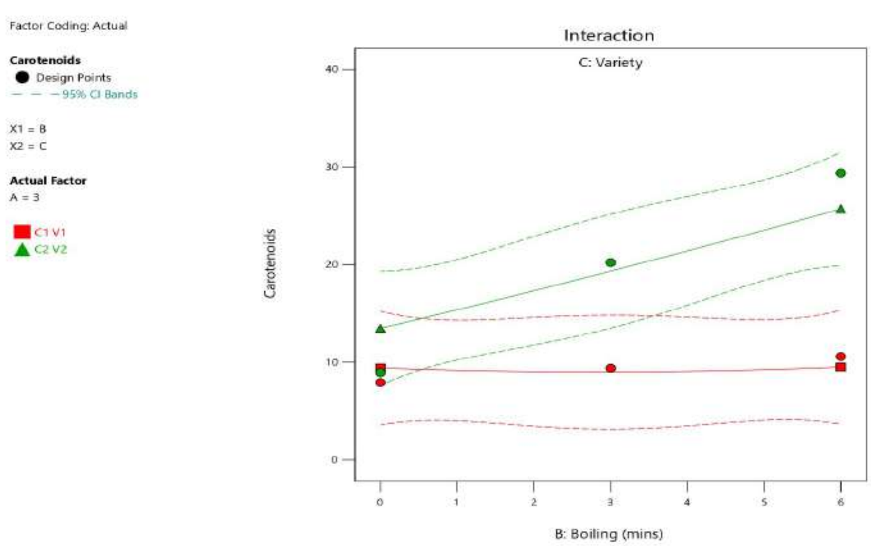

Figure 1: graph illustrating the interaction of steaming (A) and boiling (B) on the carotenoid content of pumpkin.

Optimization of the carotenoid content of pumpkin based on varied treatments

The optimization result generated 19 outputs and only 5 of the optimum desirable output were considered. The most desirable output to obtain 28.511 % of carotenoid was in second variety (Connecticut field) by steaming at 2.6 minutes and boiling for 6 minutes.

CONCLUSION

In conclusion, boiling, and time used has a substantial influence on the carotenoid content of the pumpkin varieties. However, streaming has no significant impact. The second variety (Connecticut field) was the best in terms of availability of carotene, steaming and boiling within 6 minutes can be used to enhance carotenoid bioavailability. Therefore, the inclusion of pumpkin in the diets of both children and elderly ones is recommended.

ABSTRACT
The effects of feeding diet containing boiled coffee pulp meal on haematological parameters in rabbit were studied. A total of thirty-six (36) mixed breed weaner rabbits (average weight, 550 g) were randomly allocated to four dietary treatments containing 0, 4, 8 and 12% boiled coffee pulp meal (BCPM). Diet 1 (0% BCPM)) served as the control diet. Each of the four treatments was replicated thrice and each replicate had three rabbits arranged in a Completely Randomized Design. The rabbits were fed with the experimental diets for 12 weeks. The results showed that pack cell volume, haemoglobin, mean corpuscular haemoglobin, mean cell volume and red blood cell were significantly affected by the treatments while white blood cell count, neutrophil, lymphocytes, eusnophils, basophils and monocytes showed no significant difference. It was concluded that inclusion of boiled coffee pulp meal in rabbit diets was well tolerated by weaner rabbits without any adverse health condition.
***Keyword**: coffee pulp meal, rabbits, anti-nutritional factors, boiling, haemoglobin*

INTRODUCTION

The inability of livestock farmers to supply their animals with high quality feed has been recognized as one of the technical constraints limiting livestock production in the developing countries (Okoruwa, 2015). The livestock are exposed to severe nutritional stress especially in recent time that the prices of conventional feedstuffs such as soybeans, maize and groundnut have been increasing at the same time that the availability is often a problem (Babayemi *et al*., 2006). The case has been worsened during the dry season when fodders are rare and of low nutritive value. To salvage this problem, it is necessary for the livestock farmers to explore the cheapest and readily available agricultural waste products that have high nutritive value as feed ingredient in the diet of their animals. Typical among such feed ingredients is coffee pulp. The presence of essential nutrients such as proteins, carbohydrates fibre and some minerals especially potassium in coffee pulp suggest that it could be used as livestock feed ingredient (Barcelos *et al*., 2001), nonetheless high content of anti-nutritional factors in this by-product has restricted its use as an animal feed to a large extent (Padmapriya *et al*., 2013). Therefore, total elimination or reduction of anti-nutritional factors in coffee pulp through physical, chemical or biological processing technique is of paramount important. The major limitations of these anti-nutrients are related to its physiological effects on the central nervous system and its influence can alter the constituents of the animal blood (Mazzafera 2002). The aim of this study was to determine the effect of feeding boiled coffee pulps meal on the haematological parameters of weaner rabbits.

MATERIALS AND METHODS

About 25kg of coffee pulps were collected from the coffee pulping centre, Cocoa Research Institute of Nigeria, Ibadan. The pulps were subjected to boiling process. The process involves putting sterilized coffee pulp into heat water at 100^{0}C at a pulp: water of 1:5 for 30 minutes. At this temperature, majority of hard pulps were expected to be softened, After which the boiled pulps were removed, put into sieve to drain the water, later sun dried and stored in jute bags until it was used.
Thirty-six (36) mixed breed weaner rabbits were purchased from Adeeko Farm, Ibadan, Oyo State. Before the commencement of the experiment, the rabbits were acclimatized for seven days. During this

period, rabbits were all fed control diets and were also treated against endo and ecto-parasites using sodex (dewormer) and ivomectin respectively. The animals were randomly divided into four treatment groups andach group comprised of nine rabbits. Each group was further sub-divided into three, such that replicate groups of three rabbits were obtained for each sub-group with three rabbits per replicate. The boiled coffee pulp was mixed into rabbits ration at 0, 4, 8 and 12% inclusion level designated T_1, T_2, T_3 and T_4 respectively (Table 1). All diets were formulated to meet the nutritional requirements of weaner rabbits based on NRC (2007) recommendations and the experimental diets were offered to rabbits twice in a day at about 7:00 am and 4:30 pm. The animals were allowed *ad libitum* access to feed and water throughout the trial. On the last day of the feeding trial, two sets of blood samples were collected from each rabbit via jugular vein puncture using a 5 ml needle fitted syringe. About 5 ml blood sample each was collected into labeled sterile bottles containing anticoagulant for the determination of hematological parameters while the blood samples for serum analysis were taken with sterile bottles without anticoagulant, so as to allow the blood to coagulate at room temperature. The supernatant was then collected and stored in a freezer for subsequent biochemical analysis. The blood samples were analyzed using the procedure described by AOAC (2001). Data collected from this study were subjected to statistical analysis (SAS, 2008 version 9.2) and significant means were separated using Duncan multiple range test (Duncan, 1955). The trial lasted for 84 days.

Table 1: Feed composition and calculated nutrient values of the experimental diets

Parameters	**T_1 (0%CPM)**	**T_2 (4%CPM)**	**T_3(8%CPM)**	**T_4 (12%CPM)**

^{abc}= mean with different superscripts on the same column are significantly different (P<0.05), SEM= Standard error of mean

RESULTS AND DISCUSSION

The results of haematological parameters of rabbits fed graded levels boiled coffee pulp are presented in Table 2. The results showed significant (P<0.05) differences in most of the haematological parameters investigated. The least packed cell volume (PCV) was recorded in rabbits fed control diet which increase progressively as the level of boiled coffee pulp increase in the diets. The increase in the PCV concentration in the blood of rabbits in this experiment indicated the good health status as low PCV values are taken as an index of anaemia. This is in agreement with the finding of (Abdelati *et al*., 2008) who reported reduction in the PVC of broiler chickens fed roasted *Leucaena leucocephala* at various levels and attributed it to toxic factor (anti-nutritional factor) in the diet. PCV is a symbol of toxicity (Ahamefule *et al*., 2008). Haemoglobin (Hb), mean corpuscular haemoglobin (MCH), mean cell volume (MCV) and red blood cell (RBC) counts were also significantly (P<0.05) affected by the dietary inclusion of boiled coffee pulp which increase progressively as the level of inclusion is increased in the diet. The increase in Hb, MCH, MCV and RBC denotes that coffee pulp meal positively contributed to the synthesis of blood forming metabolites such as copper, iron and magnesium which augments effective transportation of oxygen and other nutrients in the body of animals (Oyebode, 2015). The white blood cell were not significantly (P>0.05) different. This shows that boiled coffee pulp meal neither enhanced nor impaired the ability of rabbit to ward off infection. There was also no significant (P>0.05) difference in the neutrophil, lymphocytes, eusnophils, basophils and monocytes, and their values fell within the normal range established by Research Animal Resource (2009) for growing rabbits.

CONCLUSION

It was concluded that inclusion of boiled coffee pulp meal in the rabbits diet was well tolerated by weaner rabbits without any adverse health condition.

ABSTRACT
Sesame (Sesamum indicum L.) is an important oil spice grown in Nigeria with good yield obtained from savannah zone with low rainfall, hence the need for its trial in Owo, a guinea savannah transition zone. Field experiment was conducted during rainy season of 2022 at Rufus Giwa Polytechnic Teaching and Research Farm Owo, Ondo State. Three different planting dates (August 16th, August 30th and September 13th) were fitted into a Randomized Complete Block Design (RCBD) to evaluate the growth, yield and yield components of Sesame at three replications. Data were collected on vegetative and yield parameters. The results showed that August 16th planting date influenced stand count, plant height, number of leaf per plant, number of capsule per plant, number of seed per capsule, moisture content and yield as against August 30th and September 13th planting dates. Therefore, August 16th is recommended for Sesame cultivation in the study area.
Keyword: *Sesame cultivation, planting date, agro-ecology, climatic variable, yield*

INTRODUCTION

Sesame (*Sesamum indicum* L) is one of the oldest sp oil crops in the world, grown mainly for its seed that contains approximately 50% oil and 25% protein (Olowe 2007). It belongs to the family *Pedaliaceae,* which contains about 16 genera and 60 species (Olowe, 2007). Nigeria currently produces 400,000 - 500,000 tons of Sesame seed with the largest producing states being Jigawa, Nasarawa, Benue, Bauchi, Taraba, Niger, Kano, Katsina, Gombe, Kogi, Kwara, Yobe and Plateau, unfortunately, average yield of Sesame is still low at 0.4 ton/ha (FAO, 2018). Climate is one of the important factors affecting Sesame cultivation in most agro ecological zone. Commercial variety requires 90 - 120 frost-free days. Day time temperature of 20°C to 27°C is optimal, below 20°C, growth is reduced, and at 10°C germination and growth are inhibited. Rainfall requirement for Sesame ranges between 500 – 800 mm per annum (Ogbonna and Umar-shaba, 2012). It requires adequate moisture for germination, early growth and for reasonable yields (Olowe, 2007, Abdel Rahman *et al.,* 2007). It tolerates many soil types, but it thrives best on well drained fertile soils of medium texture and neutral pH.

Planting date affect the growth and yield of Sesame in different agro ecology, particularly in derived savannah zone (Olowe, 2007, Abdel Rahman *et al.,* 2007). Farmers growing Sesame in some part of south western savannah transition zone of the country have not been adequately informed on the best planting period that can give them high and quality yields. It is therefore essential to find out the best planting date for Sesame in the study zone in order to encourage its cultivation and increase the crop yield.

MATERIALS AND METHODS

The experiment was conducted at the Teaching and Research Farm, Rufus Giwa Polytechnic Owo, Ondo, (Latitude 7° 05^{N}; 5° 15^{E} Longitude), at 350m above sea level. Ondo falls under swamp forest and longtime raining season. The annual rainfall varies from 1200mm to 1420mm decreasing southwards. The maximum and minimum temperatures of the area average are 28.8°C and 15°C. The treatments consisted of three (3) planting dates; August 16, August 30 and September 13, laid out in a Randomized Complete Block Design (RCBD replicated three (3) using balloting method on 168m² area of land). The land was cleared, ploughed and harrow mechanically, using tractor and hand hoeing during weeding. The experimental plot consist of nine (9) plots measuring 4m x 1.5m (6 m²) each with 0.5m pathway between plots and 1m between replicates. *Jigida*, Hausa variety of 90 to 95days maturity was obtained from National Cereal Research Institute (NCRI), Badeggi, Niger state. Sowing was done at spacing of 20 ×50 cm intra / inter row spacing. Weeding was done twice by hand at 3 and 6 weeks after sowing (WAS). The crop was harvest when the leaves begin to turn yellow and shed. The capsules turn from green to yellow and lowest capsule on the stem were about to split open. The operation was done by cutting the stem using sickle and the harvest materials from each net plot was tied in bundle, followed by threshing, winnowing and then drying. Yield from each net plot area was measure after threshing and winnowing. The weight of threshed seeds was express as kg/net plot area and also extrapolated to t/ha. Data collected include; Stands establishment count, plant height, number of leaves per plant at 6 and 8 weeks after planting, number of capsules per plant, number of seed per capsule, The fresh weight of capsule, dry weight of capsules, percentage moisture content of capsules and total yield per hectare (t/ha)

Data Analysis

The data generated was subjected to analysis of variance (ANOVA) using procedure of Statistical Analysis System (SAS). Significant differences were separated by Duncan's Multiple Range Test (DMRT) at 5% level of significance.

RESULTS

Effect of different planting dates on the vegetative growth of Sesame at 6 and 8 WAS

Planting dates significantly influenced stand count establishment, with the 1st planting date (August 16th) having the highest count (65925.89), followed by 3rd (September 13th) with 49629.59 count and the least stand count establishment value (46481.46) recorded at 2nd planting date (August 30th). Same trend was observed for plant height. Plant height recorded significant ($p<0.05$) difference at 6 and 8 WAS in favour of 3rd planting date. There was no significant difference observed in 3rd and 1st planting dates, nevertheless 3rd planting dates was statistically different from 2nd planting date. While, 1st and 2nd planting dates were not statistically different. Number of leaf at 6 and 8 WAS were significantly ($p<0.05$) higher in 1st planting dates (41 and 49.97), followed by 2nd planting date (27 and 36.34) and the least value at 3rd planting date (22.23 and 27.96) respectively. Data obtained for stem girth at 8 WAS were statistically similar at 2nd and 1st planting dates (Table 1).

Effect of different planting dates on the yield and yield components of Sesame at harvest

Significant increase was recorded for number of capsules per plant at 3rd planting date and the least value at 1st planting date. Length of capsule, number of seed per capsule were significantly ($p<0.05$) influenced by 1st planting dates. Moisture content significantly increased at 2nd planting date while fresh weight of capsule per plant and dry weight of capsule per plant were statistically similar across all treatments (Table 2).

DISCUSSION

Planting date had a significant influence on some vegetative parameters of sesame. The significant difference in stand establishment count of sesame could be attributed to potential ability of the seed to resume active growth, based on seed physiological maturity which varies among seed lots, in the presence of germination factors prevalent at the sowing date. These factors as enumerated by Kingra and Kaur (2012) include temperature, day length, relative humidity, rainfall, wind velocity and biotic factor. This study showed that the climatic factors in the study area varies with different planting dates (Figure 1). Plant height, number of leaf and stem girth at various stages of growth, in this study showed variation that could be attributed to climatic influence of the growing period. The variation in temperature, humidity and moisture could influence root temperature which in turn affect root and shoot elongation. Meena et al. (2015) reported the effect of temperature variation on the growth and yield of groundnut agreeing with this work on the influence of abiotic factor of plant growth and development. Also, Ogbonna and Umar-Shaba (2012) recorded lower plant growth in case of delayed sowing in cucumber, noting that maximum number of leaf was obtained from August sowing to first week of September.

Mean capsule length was significantly influenced by planting date. this might be due, in part, to early sowing which enhanced availability of extended photoperiod for good vegetative growth to produce maximum capsule length. This result aligned Naoki et al., (2011) on the growth and sesamic content of sesame. Number of capsules per plant, number of seed per capsule, increased moisture content of capsule and yield per hectare of capsule were positively influenced by first planting date. Similar result reported by Ogbonna and Umar-Shaba (2012); Naoki et al., (2011) and Lei Deng et al., (2016) agreed with this study that adequate soil moisture content complementing the evaporative demand of the atmosphere and moisture replenishing potential of the first planting date translated to moisture distribution to the vegetative parts and significantly influenced capsules (fruit) formation of sesame.

CONCLUSION

Early planting (first planting date), during which growth resources are well distributed, in addition to conducive abiotic factor (Temperature, moisture, sunlight, humidity and sunlight quality) favour good growth, capsule formation and eventually seed yield of sesame in the study area. For optimum growth and yield, farmers in the study area are encouraged to adopt the first planting date for the cultivation of sesame.

ABSTRACT
Cucumbers (Cucumis sativus L.) is an important vegetable crop of Cucurbitaceae family. Yield of cucumber have increased over time with increase in application of inorganic fertilizer, but little considerations are given to consumers' health and preservation of natural environment, and this has necessitated the use of organic fertilizer as substitute for chemical fertilizers. Despite the benefits of organic fertilizers its application has not been easy because of the bulkiness, slow nutrient release and low nutrient composition. Therefore, this experiment was conducted at the Vegetable programme research field of National Horticultural Research Institute, (NIHORT), Ibadan. The treatments included three fertilizer sources (Organic Liquid fertilizer, NPK fertilizer and Control) applied at the recommended rates on three varieties of cucumber; (Greengo F1, Malvarino F1 and Marketmore) at four spacings of 75cmx15cm, 75cmx25cm, 75cmx40cm and 75cmx50cm. Results shows that application of inorganic fertilizer (NPK 20:10:10) followed by the liquid organic fertilizer can improve cucumber yield per hectare at the highest spacing of (75cmx15cm). Also, the highest yield was obtained from Malvarino F1 followed by Marketmore variety.
Keywords: *Cucumbers, Fertilizers, spacings, varieties, yield*

INTRODUCTION

Cucumber is an important vegetable crop (Eifediyi and Remison 2010). Cucumber is widely cultivated in temperate and tropical regions throughout the world (Vora, 2014). The plant is a coarse prostrate annual deep-rooted crop cultivated for its fruits which can either be eaten raw or with little processing in accompaniment with other vegetables (Eifediyi and Remison, 2010). In addition to providing valuable nutrients, cucumber add variety, taste, color, and texture to diets. Since cucumber fruits contain about 95% water, they are often recommended as natural diuretics and useful for body building. Nigeria soils are typically low in organic matter and supply through chemical fertilizers is becoming increasingly important. Fertilizer practices that maintain or increase production levels and simultaneously decrease ground water pollution potentials should be encouraged, since excessive application of chemical fertilizers can result in high soil nitrate levels after crop harvest (Gordon et al., 1993; Akintoye et al., 2002). Thus, the use of organic fertilizer needs to be encouraged in place of chemical fertilizers for health and environmental benefits. Although its use has not been easy because of bulkiness, slow nutrient release and low nutrient composition. However, the production of handy liquid and concentrated organic fertilizer is a relief to the problems, but its effectiveness must be compared with inorganic fertilizers at different intra row spacing to meet with cucumbers demand despite the reduction in agricultural land.

MATERIALS AND METHODS

Experimental Location and period

The experiment was carried out in National Horticultural Research Institute (NIHORT), Idi-Ishin, Oyo State, Southwestern Nigeria with coordinates Latitude 7^0 40' N; Longitude 3^0 85'. The zone is also characterized with mean annual rainfall between 1800mm-2500mm per annum (April-November) with temperature ranging from 24^0C to 32^0C. The experiment comprised of three varieties (Marketmore, Greengo F1 and Malvarino F1), three fertilizer sources (control, inorganic and organic) and four intra rows spacing (15cm, 25cm, 40cm and 50cm) at constant inter row spacing of 75cm. The total land area used for the experiment was 500 square meters. The field was sectioned into 72 plots of 6 square meters ($6m^2$) dimension each with one squared meter ($1m^2$) spacing in between them.

The experiment was designed as a 3 X 4 X 3 factorial experiment arranged in split split block design with three replicates. The main plots consisted of the fertilizer treatment, the sub plots were made up of the intra row and sub-sub plots contained the varieties.

The land was tilled mechanically by ploughing in all existing vegetation twice before harrowing.72 beds of dimension 3m x2m x 1m was made on the experimental site. Each bed represents one experimental plot. Each plot was marked according to the intended row spacing with pegs. The intra-row spacings are 15cm, 25cm, 40cm and 50cm at constant inter row spacing of 75cm to give plant density of 88,889, 52,632, 33,333 and 26,667 plants per hectare respectively. The seeds were sown directly into the soil on 23rd September 2021 at the rate of 3 seeds/hole. There was rainfall immediately after the seeds were sown hence make watering not necessary. About 55% of the seeds germinated about 7 days after sowing. The ungerminated seeds were supplied and the excess seedling thinned to one per stand a week after sowing. The N-P-K 20:10:10 fertilizer and the liquid organic fertilizer were applied at split dose in 2,4 and 6 weeks after planting to satisfy the recommended rate of 400kgN/ha.

The data collected were subjected to analysis of variance (ANOVA) using the general linear models (GLM) procedure of Statistical Analysis Systems (SAS, 2003).at 5% level of probability with LSD test to separate the means.

RESULTS

Influence of treatments on growth parameters of cucumber

Table 1 showed that application of inorganic N.P.K (20:10:10) fertilizer resulted in an outstanding performance in canopy development such as vine length and leaf area but the effects of liquid organic fertilizer on the vine length was not significantly different. This may be due to the absorption rate of the fertilizers and the immediate response of the plant to the fertilizer. Though the NPK 20:10:10 was easily available to the plants at steady level. The organic liquid fertilizer was readily dissolved with the soil water and may not be easily available to the plant due to run off by rain and leaching by soil water. Table 1 also indicated that all the variety responded to NPK 20:10:10 fertilizer but Marketmore had the best vine length.

Table 1: Vine length and leaf area of cucumber as influenced by fertilizer sources, spacing and variety at 2, 4 and 6 weeks after sowing.

		Vine length			Leaf area (cm3)

Mean	10.36	35.68	97.55	3314.27	1859.20	3501.96
LSD	0.12	1.39	4.15	4.36	4.36	62.51

LSD: Least significant difference at 5% level of probability
Means with the same letter in the same treatment are not significantly different.

Throughout the time of data collection i.e., 2, 4 and 6 Weeks After sowing, closer intra row spacing resulted in longer vine length but other parameters are significantly higher at 53,333 followed by 33,333 as compared to the widest plant spacing of 26,666 as shown in Table 1. The greatest leaf area was recorded in 33,333 which is not significantly different from that observed at 53,333 and 26,666 which are all significantly higher than the one recorded at 88,888 intra row spacing.

Influence of Treatments on Yield Component and Yield Parameters of Cucumber

As shown in table 2, cucumber with inorganic fertilizer application had the highest days to 50% fruiting but lowest number of fruits initiated per plant. but not significantly different from that of organic fertilizer application. The differences among number of fruits per plant for all the treatment is not significant. The table also show that fertilizer had the greatest influence on days to 50% fruiting. Table 2 it is shown that wider spacing of 33,333 produces the highest number of fruits initiated per plant and fruit weight per plant which is not significantly different from 53,333 and 26,666 but significantly different from closest spacing of 88,888. Spacing has no significant influence on number of non-marketable fruit and weight per plant but closest spacing produce the highest non-marketable fruit yield per hectare. Widest spacing 26,666 resulted in longest fruit which is not significantly higher than intra row spacing of 40cm but had a significantly higher fruit girth (Table 2).

Table 2: Yield and yield component of cucumber plant as influenced by fertilizer, spacing and variety.

DISCUSSION

The results of NPK Fertilizer on both the vegetative and yield parameters of cucumber was significantly higher followed by organic liquid fertilizer. Though, it is expected that NPK fertilizer should improve the growth of cucumber as reported on other nitrogen loving crop. However, the application of NPK fertilizer resulted in excessive foliage growth that delayed reproductive stage of cucumber. The slow release of N from the organic fertilizer source resulted in the slow pace of development but it did not have negative effect on yield parameters. NPK fertilizer effect on fruits' parameters was higher than that of liquid fertilizer. This implied that NPK fertilizer seems to improve the fruit length, girth, weight, and the number of fruits produced. This conforms with the findings of IwaIewa *et al.,* (2019) who reported that NPK fertilizer perform best in enhancing cucumber production when compared with other fertilizer sources. It is also in line with the findings of Akintoye and Olaniyan., (2023), who reported that sweet corn yields with applied inorganic fertilizer were greater than those receiving organic sources of fertilizer. Vikash Kumar et al. (2016) who attributed the vigorous growth and increased fruit yield of cucurbits to higher supply of nutrient elements also supported this outcome.

The Mean Square table showed that spacing also significantly produced variations in the vegetative values observed. Widest spacing 26,666 plants ha^{-1} and 33,333 plants ha^{-1} contributed significantly to the highest canopy cover. This is in line with Vinkash *et. al*., (2016) who observed that closer spacing resulted in significantly lower total above-ground plant dry weights, growth rates, and total leaf areas for cucumber cultivars. Widest spacing 26,666 plants ha^{-1} resulted in longest fruit which is not significantly higher than wider intra row spacing 33,333 plants ha^{-1} but had a significantly higher fruit girth. However, closest spacing 26,666 plants ha^{-1} produced the highest fruit yield per hectares while widest spacing produced the least which is not significantly different from that of wider spacing 75cmx40cm. Similar result supported this in the work done by Sanni and Adenubi (2019). The effects of intra row spacing observed on the cucumber plant may be attributed to varying level of intra specific competition caused by the four-plant spacing. Makinde and Macarthy: (2014) reported that this competition effects may be completely absent until a threshold at which resources becomes limited is reached. These findings are in line with Streck et al, (2014) who reported that final leaf size and lateral shoot growth of cassava increased as the spacing increased (i.e., decreased planting density). It also corroborates results reported by Enujeke (2013).

CONCLUSIONS

The results suggests that the use of NPK 20:10:10 inorganic fertilizer is best for commercial cucumber production in Southwestern Nigeria. This is because N-P-K 20:10:10 increases vegetative growth and canopy formation hence can produce more assimilates which later converts to useful biomass. Although closest spacing of 88,888 plants ha^{-1} had the highest yield per hectare, wider spacing of 33,333 plants ha^{-1} performed better in many other attributes such as fruit length, fruit girth, number of fruits per plant and fruit weight per plant probably because spacing is necessary for widening of leaves and thickening of vine.

ABSTRACT
The experiment was conducted at the Teaching and Research Farm of the Federal University of Technology Minna, during the 2019 and 2020 cropping seasons. The treatments consisted of 2x5x6 factorial combinations of two okra cultivars (NHAe47-4 and LD 88), five nitrogen rates (0, 30, 60, 90, and 120 kg ha-1) and six fruit positions on the mother-plant (1, 2, 3, 4, 5 and 6th) arranged in a Completely Randomized Design (CRD) and replicated four times. Parameters measured includes number of seeds, seed weight and germination percentage. Data collected were subjected to analysis of variance (ANOVA) using SAS Statistical package 9.2. At 5% level of probability means were separated using Least Significant Difference (LSD) Test. Application of 120 kg N ha-1 produced the highest number of seeds and seed weight of okra. Harvested fruits from the lower positions (1-2) gave best results in all the parameters. While seed germination was greater at the lower positions prior to storage and after storage.
Keywords: *Okra, Seed size, Fruit position*

INTRODUCTION

Okra (Abelmoschus esculentus (L.) Moench), an economically important vegetable crop grown in tropical and sub-tropical parts of the world, also known as Ladies' Finger, originated from Ethiopia (Pandey et al., 2017) and was then propagated in North Africa, in the Mediterranean, Arabia and India by the 12th century BC (Nimona, 2019). It is one of the most widely known and utilized species of the family Malvaceae (Dantas et al., 2021). Okra grows best on well-drained sandy loam soil; it prefers slightly acidic soils with a pH between 6.0 and 6.8 (Nisar et al., 2021). The minimum and maximum soil temperatures for growth are 20°C and 30 °C, respectively and relative humidity of 21% – 30% (Makinde, 2022).

Good seed nutrition of the mother-plant during growth is important as it has been reported (Yakubu and Abubakar, 2017) to result in rapid seedling emergence in okra varieties. The mother-plant has a significant influence over seed traits, including seed size, dormancy, germination and storage. In many species, factors such as age of the mother-plant and position of the seed in the fruit, inflorescence, or canopy can affect seed properties (Lu et al., 2017). Seed quality is also affected by several factors and seed germination, vigour and health assessment play an important role in determination of seed quality (Ndinya et al., 2020). Seed vigour is an important factor that affects seedling establishment and crop growth and ultimately production rate. The seed lot may differ in size, number and weight which may be affected by growing conditions and cultural practices (Adebisi et al., 2021). Adebisi et al. (2011) reported that seed size, number and weight are components of seed quality which affects the performance of crop. The study was carried out to determine the impacts of nitrogen rates on seed quality of okra at different fruit positions.

MATERIALS AND METHODS

A Field experiment was conducted at the Teaching and Research Farm of the Federal University of Technology, Minna (latitude 90 51 1N and longitude 60 44 1E) during the 2019 and 2020 cropping seasons (May-Sept). Before land preparation, soil samples were collected from surface (0-15cm) with an auger from 10 points along four diagonal transects, each bulked together to give four composite samples. The soil samples were air dried and sieved through 2mm and 0.5mm sieve. They were analyzed for particle size distribution, pH 1:2 (H_2O and $CaCl_2$), Organic carbon, total nitrogen, available phosphorus, exchangeable bases (Ca^{2+}, Mg^{2+}, K^+, Na^+), exchangeable acidity (Al^{3+} + H^+) and effective cation exchange capacity following the procedures as described by Agbenin (1995). Seeds of NHAe47-4 and LD 88 variety of okra were sourced from the National Horticultural Research Institute (NIHORT) Ibadan, Oyo State Nigeria.

The land was manually cleared and ploughed with a tractor and ridges were constructed manually at 75 cm apart each measuring 2 m long. Plots were measuring 2×5.25 m (10.5m2) comprising of 8 ridges. The treatments consisted of factorial combinations of two okra cultivars (NHAe47-4 and LD 88) five nitrogen rates (0, 30, 60, 90, and 120 kg ha-1) and six fruit positions on the mother-plant (1, 2, 3, 4, 5 and 6th) arranged in a Completely Randomized Design (CRD) and replicated four times. Three seeds were manually sown per hole at 0.5m apart and later thinned to one vigorous seedling per stand (2WAP). Basal application of Phosphorus using single super phosphate and muriate of potash as sources and split application of varying rates of urea as a source of N fertilizer at 50 kg ha-1 each was applied in all the plots 2 week after planting (WAP) respectively. . The first application was at 2 WAP and second application was at 4 WAP (before flowering). Weeding was carried out at two weeks intervals manually.

Incidence of insect pests was suppressed from 2WAS till harvesting stage with the application of Zap® a.i (Lambda Cyhalothrin 25g/L), at 0.005kg a.i/ha. . Plants were date tagged at flowering daily on the field. The tagged fruits were harvested at different positions on the mother-plant (1, 2, 3, 4, 5 and 6) at 42 DAA (Days after anthesis). Following each harvest, the fruits were broken to extract the seeds. The seeds were left to dry further at ambient temperature for about two weeks before storage. Samples of seeds from each treatment combinations were put in small open plastic plates measuring 300 ml and then placed in an incubator at 35 ºC and relative humidity of 90 %. This was aimed at accelerating the ageing of the seeds to determine the relative longevity of the seeds of the different lots (Delouche and Baskin, 1973). The okra seed samples were drawn from the containers in storage for conducting germination test at 0, 2, and 4 weeks after storage. This was done by counting four replicates of 30 seeds of the seven harvesting stages which was placed on filter paper moistened with distill water in plastic Petri-dishes. Germination counts was taken every-other-day and results were expressed in percentages. Parameters measured included Number of seeds, seed weight and germination percentage

The data collected were subjected to analysis of variance (ANOVA) using SAS Statistical package 9.2. At 5% level of probability means were separated using Least Significant Difference (LSD) Test.

RESULTS

The results of the chemical and physical properties of the soil at the experimental sites before the two cropping years 2019 and 2020 are presented in the Table 1. The particle size distribution showed that the soil of the site is loamy sand in texture with a moderate pH indicating the soil to be slightly acidic (H_2O) 6.7, 6.8 and (CaCl) 5.5, 6.1 respectively. Soil organic carbon (SOC) of 4.50(g kg-1), 4.51(g kg-1) and Soil Total N of 1.21 (g kg-1), 1.23(g kg-1) was found to be low. The available phosphorus 8.25, 8.50 (mg kg-1) and ECEC 8.2, 7.69 (cmol+ kg-1) respectively of the soil were also found to be low. The Exchangeable bases (Cmol+ kg-1) Ca^{2+} 3.75, 3.85, K^+ 0.07, 0.03 and Na^+ 0.17, 1.55 respectively were considered to be moderate. The exchangeable Mg^{2+} 3.0, 2.90 was considered sufficient to support plant growth.

The effect of nitrogen rates on number of seed of two okra varieties at different harvesting positions in 2019 and 2020 is shown in Table 2. Number of seed was significantly different among the okra varieties at harvesting position 1 in 2020 only, such that LD 88 produced the highest number of seed (72.47) than NHAe47 – 4 which produced the lowest number of seed (68.0). Nitrogen rates had a significant effect on number of seed throughout the sampling positions in 2019 and 2020 respectively. At position 1, the application of 120 kg N ha-1 produced the highest number of seed in both years (88.33 and 87.50) than the other rates compared with zero application in 2019 (39.88), 0 and 30 kg N ha-1 in 2020 (51.83 and

58.00) which produced the lowest number of seeds. At position 2 in 2019, the application of 60, 90 and 120 kg N ha-1 produced significantly similar highest number of seeds (62.50, 67.67 and 65.33) than zero application which had the lowest number of seed (38.83). In 2020, the application of 90 and 120 kg N ha-1 produced statistically similar highest number of seed (69.17 and 75.33) than the application of 60 kg N ha-1 (62.17) compared with 0 and 30 kg N ha-1 which recorded similar lowest number of seed (44.17 and 50.17). At position 3 in 2019, the application of 90 and 120 kg N ha-1 produced similar highest number of seed (69.17 and 75.33) compared with 0 and 30 kg N ha-1 which had similar lowest number of seed (44.2 and 50.2).

The effect of nitrogen rates on seed weight of two okra varieties at different harvesting positions in 2019 and 2020 are shown in Table 3. Seed weight differed significantly across the positions and years except at position 1 in 2019, position 4 and 5 in both years and position 6 in 2020 which showed no significant difference among the varieties. The variety LD 88 consistently produced the heaviest seeds between (3 g – 5 g) than NHAe47 – 4 which consistently produced the lightest seeds between (3 g – 4 g) across the years. Nitrogen rates affected seed weight significantly throughout the sampling periods in 2019 and 2020 respectively. At position 1, the application of 120 kg N ha-1 produced significantly heavier seeds in both years (6.25 g and 6.07 g) than the other rates compared with zero application in 2019 (3.03 g), application of 0 and 30 kg N ha-1 in 2020 (4.09 g and 4.3 g) which produced the lightest seeds. At position 2 in 2019, the application of 60, 90 and 120 kg N ha-1 produced statistically similar heaviest seeds (4.45 g, 4.65 g and 4.59 g) than zero application which had the lightest (3.22 g). In 2020, the application of 120 kg N ha-1 produced significantly heavier seeds (5.11 g) similar with the application of 90 kg N ha-1 (4.18 g) compared with 0 and 30 kg N ha-1 which had similar lightest seeds (3.66 g and 3.88 g).

Table 4 showed variety significantly affected germination percentage of seeds at different storage periods at 0 weeks before storage (WAS). Seeds of NHAe47-4 germinated significantly higher 49.57% than LD88 43.50 % in 2019 while in 2020 LD88 recorded 54.25%) than seeds of NHAe47-4 51.61%. In 2019, at 2 WAS varieties significantly differed statistically in both years respectively. NHAe47-4 recorded higher germination 46.25% than LD88 39.02%. While in 2020 the reverse was recorded where LD88 germinated significantly higher with 35.92% than NHAe47-4 32.89%. The same trend affected the traits significantly at 4WAS. However, position affected germination percentages significantly across storage periods. Prior to storage, seeds extracted from fruits of positions 1 and 2 germinated significantly higher (61.50% and 58.85%) than those of positions 3-6 with values ranging between 50.40 and 27.90% in 2019. In 2020, seeds from positions 4 and 3 germinated significantly higher 77.47 and 76.03%.

DISCUSSION

Rao et al. (2017) advised that seeds should be harvested at appropriate time to ensure their quality in terms of germinability and vigour. However, Bortey et al. (2022) reported that fruits harvested even before physiological maturity and allowed some days of post-harvest ripening may produce good quality seeds since seed development continues in fleshy fruits owing to continuous supply of nutrients and food reserves from fruit to seed. Kortse and Oketa (2016) also observed that okra fruit size was affected by position on mother-plant under competition for assimilates. Seeds from the peduncular fruit segments were delayed in reaching maximum quality compared with seeds from other positions in cucumber (Hu et al., 2019). Bigger seeds in the earlier positions than in later ones (position 6) is due to the fact that less nutrients were made available to the developing fruits and seeds of later positions (Ibrahim and Oladiran, 2011). Position 1 fruits weighed the heaviest compared to those of the other positions (2, 4, 4, 5 and 6) on the mother-plant, this result agrees with the trend reported by Alan and Eser (2007) for pepper in which fruit weight gradually declined from position closest to the plant base to those at the upper layer.

CONCLUSION

Fruits formed at the lower positions (1-3) produced more and bigger seeds than those formed at the higher positions (4-6).

Position of fruits on the mother-plant

Table 1: Physical and chemical properties of the soil samples of the experimental field

Soil Properties	2019	2020
Particle Size distribution (g kg^{-1})		
Sand	815.5	8.17

ABSTRACT
To investigate the appropriate time of harvest for four cultivars of bell-pepper (Capsicum annuum), a mass transplanting of "Dan Datsa", "Dan Charkawa, "Dan Damaso", and "Dan Boko" cultivars of "tatashe" was carried out in the 2018 dry season at 75 × 50 cm inter-row and intra-row spacings respectively. Each cultivar was transplanted in dedicated blocks measured at 108 m^2. The flowers were tagged at full anthesis, and the fruits were harvested at 25, 30, 35, 40, 45, 50 and 60 days after anthesis (DAA). Seeds were extracted, processed, packaged, and stored in an incubator set at 35 °C and 75% relative humidity (RH) to accelerate the ageing process of the seeds. Samples were collected every week for viability test and monitoring of seed protein content. The seeds of "Dan Damaso" cultivar recorded significantly higher (36.57 - 1.57%) seed germination percentage (SGP) and significantly higher seed protein content (23.78 – 18.24%) which was across the storage period. While other cultivars recorded germination ranging between 0.50 - 31.71% germination and 16.31 – 21.34% SPC. Fruits harvested at 50 DAA recorded significantly higher SGP and SPC across the storage period. Across the storage period, irrespective of harvesting stages, SGP recorded increase in values within the first 2-3 weeks of storage while the SPC values reduces as the storage period progressed. From this study, we can conclude that studying the seed protein contend of bell-pepper seeds can be used to monitor the viability and vigour of bell pepper seeds during storage.
Keywords: *ageing process, full anthesis, seed protein content, storage period, viability test*

INTRODUCTION
Globally, pepper is a very important vegetable crop for both fresh and processed food markets (Airaki *et al.,* 2012). Over 200 million Nigerians irrespective of their socio-economic status use pepper extensively for either, colouring, flavouring, soup making, or stew thickening (Gates *et al.,* 2007). However, seed production in Nigeria has been undermined by the incidence of pests, diseases, high cost of inputs (pesticides, herbicide, and fertilizer), land over-utilization, and poor-quality seeds (Kudi *et al.,* 2008). Also, majority of seed companies in Nigeria place a high priority on the production and distribution of cereals and legumes leaving the small-holder vegetable farmers to source seeds by themselves. These small-holder farmers mostly collect seeds and fruits that have been left to weather on the field which are of poor quality (Ibrahim *et al*. 2017).
Oladiran and Kortse (2002) stated that the production of high-quality vegetable seeds is dependent on genotype and the appropriate time of harvest. During the fruit maturation process, seeds go through physical, biochemical, and physiological changes which are influenced by genetic (Makhaye *et al.,* 2021) and environmental (Kurukalasuliya *et al.,* 2013) factors. Ibrahim *et al.* (2017) reported that both mass and physiological maturity of seeds were attained in all four genotypes of pepper used at 52 days after anthesis (DAA). Vigidal *et al.* (2009) reported that the vigour of sweet pepper seeds extracted from fruits that were harvested at 60 or 70 days after anthesis was higher than those obtained from fruits harvested at 40 or 50 days after anthesis. A vigorous lot have both the high percentage of viable seeds in the sample and can also produce normal seedlings under in less than optimum or adverse conditions like what is obtainable on the field (ISTA, 2021). Using a vigorous seed not only results in fast and uniform

germination but also assists in competing with weeds on the field for water, light, and soil nutrients (Cheng *et al.,* 2015).

According to Vandamme *et al.* (2016), seed weight and seed nutrient content affect plant growth and seedling state. Previous research related seedling vigour to seed size and its protein concentration (Han *et al.,* 2014). Snider *et al.* (2016) listed seed mass, total oil, and protein calorie content to be associated with early seedling vigour of cotton. Wen *et al.* (2018) used the absolute protein content (APC) of wheat seed to evaluate the plant's dry matter and assess seed vigour. In this research, we assess the variation in seed protein content among four bell pepper cultivars and monitor the changes in protein content as the seed ages. Secondly, the relationship between fruit age, seed protein content and their influence on seed vigour was also monitored as the seed aged. Therefore, the objective of this research is to evaluate viability and vigour by measuring their seed protein content.

MATERIALS AND METHODS

Seeds from the four cultivars of bell-pepper used ("Dan Datsa", "Dan Charkawa", "Dan Damaso" and "Dan Boko") and harvested at seven different fruit maturation stage (25, 30, 35, 40, 45, 50 and 55 days after anthesis) in a factorial combination of 4 × 7 arranged in a completely randomized design (CRD) and replicated four times. Twenty-eight different seed lot of bell-pepper were placed in plastic containers with perforated lids which were stored in an incubator set at 35°C and 75% relative humidity to accelerate the ageing process of the seeds. Samples were taken every week, or every order week and the following was evaluated.

Seed germination percentage (SGP): The seed germination percentage was determined by counting 50 seeds from each lot and placing them on a moistened paper towel. They are observed for two weeks, and germination count is conducted every-order-week and expressed in percentage.

Seed protein content (SPC): About 0.5g of sample was taken and added into the digestion tube where also 20ml of concentrated sulphuric acid was added. One selenium tablet was added as catalyst. The content in the tube was heated at a temperature of 35^{o}C for 6 hours until a clear digest was achieved, that is a clear solution. This solution was poured into a standard flask and made up to 100ml (Wen *et al.,* 2018). The data collected on all the parameters were subjected to analysis of variance (ANOVA) using Statistical Analysis System (SAS) and where significant differences among the treatments are obtained, means were separated using the Duncan Multiple Range Test (DMRT) at 5% probability unless otherwise stated.

RESULTS AND DISCUSSION

Figure 1 shows that seeds extracted from "Dan Damaso" cultivar fruits did not only record significantly higher seed germination percentage (SGP) during storage but also broke its dormancy faster by attaining its highest SGP (36.57%) at an early 2 weeks after storage (WAS). Other cultivars, "Dan Datsa", "Dan Charkawa" and "Dan Boko" attained their highest SGP values (20.29, 18.5 and 17.0% germination) at a later 3 WAS respectively. Seeds extracted from the fruits of "Dan Charkawa" cultivar recorded significantly lower SGP values which ranged between 0.5 and 17% germination during the 8 weeks of storage although the values were statistically at par with those of "Dan Datsa" between 4 WAS up until the end of storage (8 WAS).

Dormancy has been reported to be present in freshly harvested seeds of *Solanum spp* (Yogeesha *et al.* 2008) and this dormancy was also reported by Oladiran and Kortse (2002) to vary among pepper types. Ibrahim et al. (2018) also observed variation in viability among pepper genotypes. The variation in SGP and dormancy levels among the four cultivars of bell pepper used could be ascribed to their genetic make-up. Ramirez-Rosales *et al*. (2004) also reported variations in germination percentages among tomato genotypes which they attributed to the low germination in some cultivars due to their high lycopene content. High lycopene content is also attributed to high ABA content (Seyed and Naser, 2012). Abscisic acid (ABA) and gibberellins (GA) are well-known phytohormones that are involved in regulating seed germination. The two hormones operate in opposite manners, as the ABA inhibits germination while the GA promotes the biological process of germination (Nambara *et al.,* 2010).

Figure 2 shows the effects of fruit harvesting stages on the SGP of bell pepper plants. Seed extracted from fruits that attained 50 days after anthesis (DAA) recorded significantly higher SGP values during storage with values ranging between 2.87 and 43.25% at 8 and 2 WAS respectively. Seeds extracted from fruits harvested at 25 DAA produced seeds with significantly lower SGP values during the periods of storage. These values ranged from 0.00 to 7.38 recorded at 8 and 3 WAS respectively. This suggests that at 50 DAA maximum seed filling, sufficient nutrient absorption of soil nutrient which is translocated into the seeds in the fruit has occurred. This process might have conferred superiority in the capacity of these seeds over those of other ages. This was similar to the findings of Demir and Samit (2001) who reported that harvesting tomato when they are fully red, and firm (70DAA) gave the maximum seed quality regardless of the seed extraction method used.

Figure 1: Effects of cultivar on seed germination percentage of bell pepper plants

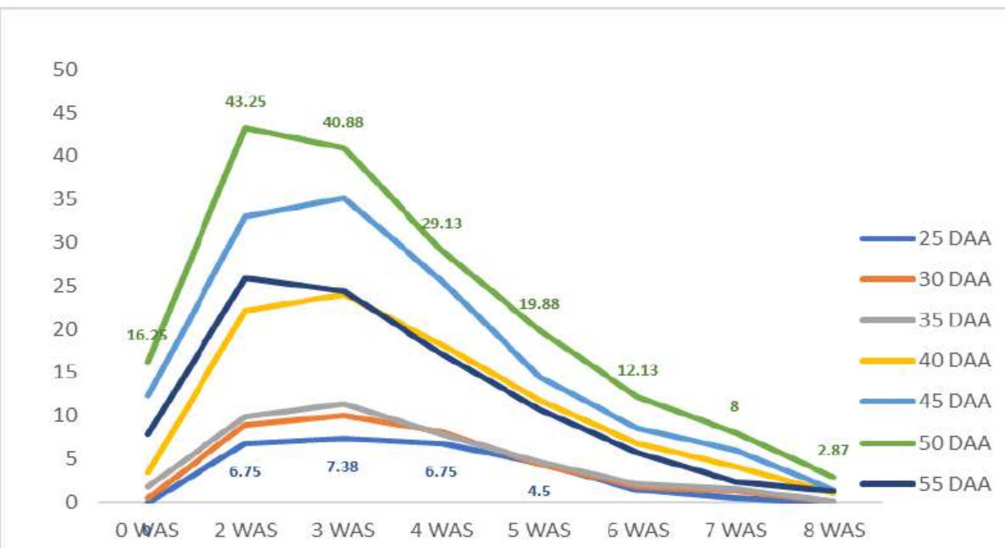

Figure 2: Effect of fruit age on seed germination percentage of bell pepper plants

Table 1 shows the interaction effects of cultivar and fruit age on the SGP of four bell pepper harvested at different fruit ages. Seeds extracted from the fruits of "Dan Damaso" cultivar and harvested when the fruits attained 50 days after anthesis produced seeds with significantly higher SGP values across the period of storage. These values ranged from 73.50% obtained at 2 WAS and 4.00% germination obtained at the end of storage (8 WAS). Irrespective of cultivar, seeds extracted from fruits that attained just 25 DAA recorded the lowest SGP values across the 8 weeks of storage.

Figure 3 shows the effects of cultivar on the seed protein contents (SPC) of four bell-pepper plants. "Dan Damaso" cultivar of bell-pepper produced seeds with significantly higher SPC during the storage period with values ranging between 23.78% recorded at the onset of storage (0 WAS) and 18.24% protein recorded at end of storage (8 WAS). Seeds extracted from the fruits of "Dan Boko" cultivar recorded the least SPC with values ranging from 19.13% protein at 0 WAS and 16.31% protein at 8 WAS. Adepoju *et al.* (2019) observed varying types of protein bands among "Ijosi" and "Sombo" varieties of pepper. According to Gao *et al.* (2016), the content of storage proteins is one of the main determinants of seed longevity. This statement is supported by the fact that the biggest differences between seeds with high and low quality are seen in their storage proteins (Sathish *et al.,* 2015). The superiority of "Dan Damaso" cultivar in seed protein content could be as a result of its ability to assimilate more nutrient required for protein production and also has the capacity to translocate more of this nutrient into the seed.

In figure 4, at 2 WAS, seeds extracted from fruits that attained 40 DAA recorded significantly high SPC value (21.58% protein), while at 0, 4, 6 and 8 WAS seeds extracted from fruits that attained 50 DAA recorded significantly higher SPC values with 25.51, 22.53, 21.75 and 20.08% protein. Fruits that attained 25 DAA before harvest produced seeds with significantly lower SPC values across the period of storage. These values ranged between 16.91 and 14.99% protein recorded at 0 and 8 WAS. The interaction between cultivar and fruit age on the seed protein content of bell-pepper plant is shown on Table 2. The table shows that fruits of "Dan Damaso" cultivar that attain 50 DAA produced seed that contains significantly higher SPC (27.28, 24.34 and 20.18% protein) recorded at 0, 2 and 6 WAS respectively. Fruits of "Dan Boko" cultivar that were harvested when the fruits that attained 25 DAA recorded the lowest SPC (15.26, 14.14 and 14.64% protein) across the storage period.

This could be tied to the fact that matured seeds have more storage reserves, desiccation, dormancy induction, better seed coat formation, and protective chemical synthesis (Naoto *et al.,*2016). Zhang, *et al.,* (2020) supported this claim by postulating that during the aging process in seeds, the changes include alterations in membrane, protein composition, disruption of the nuclear envelope, protein degradation, decreases in lipid content, oxidative stress, and decreases in mRNA translation and DNA replication capabilities.

CONCLUSION

The study further established that seed protein content has a direct correlation with seed viability, vigour and longevity. The cultivar "Dan Damaso" seeds extracted from fruit that attained 50 days after anthesis before harvest produced seeds that were more viable and contain higher percentages of seed protein content. Therefore, monitoring seed protein content during storage can be used to monitor bell pepper seed viability and vigour.

ABSTRACT
Ixora duffi is a genus of flowering plants in the family Rubiaceae in which difficulty in rooting is often encountered during its propagation. To solve this problem, the current experiment was designed to investigates the effects of different growing media on rooting and shoot development of Ixora duffi at the Ornamental Horticulture Nursery Farm, Federal College of Agriculture, Akure, Ondo State, Nigeria between May 20, 2022 to September 23, 2022. Treatment consisted of eight treatments (Top soil (TS), Sawdust (SD), Poultry Manure (PM), River Sand (RS), Topsoil + Poultry Manure (Ts, Pm), Topsoil + Sawdust (Ts, Sd), Topsoil + River Sand (Ts, RS,), Topsoil + River Sand + Poultry Manure + Sawdust (Ts, Rs, Pm, Sd). Treatments were arranged in completely randomized design and replicated three times. Cuttings were raised in polythene pots filled with the different treatment. Data collected include; days to 50% bud break, plant height per plant, number of leaves per plant, numbers of branches per plant and were subjected to analysis of variance (ANOVA) and means were separated using Duncan multiple range test at 5% probability level. TS, PM, TS+PM, TS+SD, TS+RS were early in bud break by producing 50% bud break at 15days. TS+SD produced the highest plant height with mean value of 17.43. Number of branches and Number of leaves was high in RS compare to other growth media. The study therefore conclude that RS could be used to grow Ixora duffi while TS, TS+PM and PM, TS+SD as well as TS+RS can be considered when early bud break is of high priority.

INTRODUCTION
Ixora duffi is a brightly coloured plant, a genus in the family Rubiaceae which happened to be the only genus in the tribe Ixoreae. The plants possess leathery leaves, ranging from 3 to 6 inches in length, and produce large clusters of tiny flowers in the summer. It is a suitable choice for bonsai, landscape beatification and floral arrangement. The Growers and flower nurserymen in most part of the world especially South Western Nigeria do encounter difficulty in propagation and rooting success of *I. duffi*. Larson (1980) mentioned that the best growing media must have a pH conducive to plant growth, a structure that will permit gaseous exchange to provide aeration for the root and permit water infiltration and movement. According to Kambooh (1984), organic matter content of the planting medium has a profound effect on its biological, chemical and physical properties. *Ixora duffi* plant is an acid-loving plant and grow best in acidic, rich, well-drained soil.

MATERIALS AND METHODS
The experiment was carried out at Ornamental Horticulture Nursery Farm, Federal College of Agriculture, Akure, Ondo State, Nigeria between May and September 2022. The experimental design used was a Completely Randomized Block (CRD) with three (3) replications, having eight (8) treatments

which include Top soil (TS), Sawdust (SD), Poultry Manure (PM), River Sand (RS), Topsoil + Poultry Manure 1:1 (Ts, Pm), Topsoil + Sawdust 1:1 (Ts, Sd), Topsoil + River Sand 1:1 (Ts, RS,), Topsoil + River Sand + Poultry Manure + Sawdust 1:1:1:1 (Ts, Rs, Pm, Sd). Poultry manure and topsoil were collected from the poultry unit of the Federal College of Agriculture, Akure. River sand were collected within Federal College of Agriculture, Akure. Sawdust was collected in Oba-Ile area, Akure in Ondo State. Data collected include; Days to 50% bud break, Number of leaves per plant, Plant height (cm) per plant, Number of branches per plant taken every 2weeks interval. Data collected were analysed using Gen Stat Discovery Edition 4 (version 2013) following analysis of variance procedures. The means were separated using Least Significant Difference at 5% probability level and ranked using Duncan Multiple Range Test (DMRT).

RESULTS

Effect of growth media on Days to 50% bud break

Growth media had significant effect on the cuttings of *Ixora duffi* (Table 1). The cuttings planted in TS, TS+PM, TS+SD, TS+RS were early in bud break (15 days) compare to RS, SD, PM and TS+PM+SD+RS. Late bud break was recorded in plants raised on SD+PM (23 days).

Effect of growth media on Plant Height (cm) per plant of *Ixora duffi*

Growth media produced significant ($P < 0.05$) difference on plant height with TS+SD having the highest mean plant height at 4 (17.43cm), 6 (16.37cm) and 8 WAP (13.27cm) respectively (Table 2). At 10 and 12 WAP, growth media produced significant ($P < 0.05$) difference on plant height with RS having the highest plant height with mean value 13.22cm and 11.12cm respectively while TS+PM had the least plant height (0.00cm) in both weeks. At 14, 16 and 18 WAP, there was no significant difference in the effect of growth media on plant height of *I. duffi*.

Effect of growth media on Number of Leaves per plant of *Ixora duffi*

Growth media produced significant ($P < 0.05$) difference on number of leaves of *I. duffi* with TS+RS having the highest number of leaves (6.67) while SD had the lowest number of leaves (1.89) at 4 WAP. At 8 WAP, growth media produced significant ($P < 0.05$) difference with TS+SD produced the highest number (4.67) of leaves (Table 3). At 10 WAP, growth media produced significant ($P < 0.05$) difference on number of leaves of *I. duffi* with PM having the highest number of leaves (5.89) while TS+PM had the lowest number of leaves (0.00). At 12 WAP, growth media produced significant ($P < 0.05$) difference on number of leaves with RS having the highest number of leaves (5.56) while TSPM had the lowest number of leaves (0.00). At 6, 14, 16 and 18 WAP, there was no significant difference in the effect of growth media on number of leaves of *I. duffi*.

Effects of growth media on Number of Branches of *Ixora duffi*

The growth media effects on number of branches of *I. duffi* was significantly ($P < 0.05$) different with TS having the highest number of branches (2.56) at 4WAP, while SD had the least (0.89) number of branches (Table 4). At 8, 10 and 12 WAP, growth media had significant ($P < 0.05$) effect on number of branches with RS having the highest plant height with mean value 1.89, 1.89 and 1.67 respectively while TS+PM had the least number of branches (0.00) in both weeks. At 14, 16 and 18 WAP, there was no significant difference in the effect of growth media on number of branches of *Ixora duffi*.

DISCUSSION

The result of this study depicted differential response of *I. duffi* plants to different growing media. This is related to the observation made by Adams *et al*. (2003) that a good soil medium is the basic resource in producing healthy and thriving plants. The differential response in number of leaves, plant height and number of branches of *I. duffi* plant based on the different growing media imposed may be due to the nature, type and composition of the growing media used in this study. In addition, the nutrient availability and release might have influenced the physiological processes taking place within the plants that brought about changes at different stages of plant growth and development. Similarly, number of leaves per plant produced on medium of TS+RS at 4 WAP, TS+SD at 8 WAP, PM at 10 WAP and RS at 12 WAP were significantly higher than TS alone, SD alone, TS+PM. +PM, TS+SD, TRRS+PMSD media. This trend may not be unconnected with the assertion made by Olosunde and Fawusi (2013) that the best medium for raising ornamental plants is the soil which has heterogeneity with regard to physical properties (i.e. texture, structure, colour, bulk density and water holding capacity) and chemical properties (i.e. PH and nutrient status).

The TS (loam) and the TS+SD proved to be more drained and more aerated thereby promoting rapid absorption of nutrients leading to growth as reported by Yusuf (2009). With regard to plant height per plant, TS+SD produced significantly higher plant height especially at 4 WAP. This may be due to presence of nutrient in both media for growth requirement which promoted growth and adequate aeration. This is in agreement with the findings of Beardsell and Nichols (1982) that the physical composition of the medium can have a profound effect on the supply of air and water to the growing medium. The mixture of TS with SD had better porosity and ability for to retain moisture and inherent nutrient contained in the TS which enhanced early leaf development. This result agrees with the findings of Okunlola and Oyedokun, (2016), who opined that the porosity of SD medium when mixed with an appropriate medium could have allowed water to be imbibed in seeds and adequate aeration for early plant development. Although, river sand has good aeration and drainage, but low water holding capacity and gave lower growth value in this study (Okunlola, 2016). The TS+SD medium produced significantly higher plant height than the other media types.
This could be attributed to availability of nutrients, adequate drainage, better aeration and low bulk density in the medium. Similar observation was made by Adams *et al*. (2003) who reported on the effect of different growing media on the growth of *Dieffenbachia maculata* that plants confined to a container needs a rich, porous medium for their growth and better seedling establishment. According to Adams *et al*. (2003) the TS+SD medium gave significantly higher plant height per plant throughout the sampling periods except in the wet season where there was no difference with TS medium. This is in accordance with the findings of Lamont and O'Connell (2007) who reported that the quality of container grown ornamental plants is in broad terms dependent on the physical and chemical composition of the medium and the growing environment among other things.

CONCLUSION

The suitability of the rooting medium depends on the species, type of cuttings, growing conditions, season of the year and the cost effectiveness of the medium components. A media which is light, rich, porous, well drained and free from pathogens is considered ideal for growing of ornamental plants. A good potting medium must be easy to supply, process and a cheap source.
The study was designed with the objective to determine the proper type of growing media for the propagation and nursery production of *Ixora duffi*. The result from the study revealed that growing media significantly influenced early bud break, plant height, root and shoot growth performance of the *Ixora duffi*. The study further shows that River sand had significant effects on shoot growth and development of *Ixora duffi.* Therefore, it can be concluded that River sand as a growing media is very important for the rooting, early sprouting and shoot growth of *Ixora duffi*, thus recommended for its propagation.
Further investigation should be carried out on preparation of mixture of growth media from locally available materials and more commercial mixtures should be researched on and be available for the end users.

ABSTRACT
In the low altitude, semi-arid tropics of Jigawa, northern Nigeria, potato production is constrained by a lot of production factors such as adaptable varieties, seed form, time of planting, and storage conditions among others. Research is therefore required to address these constraints. Consequently, a field trial was conducted at Kazaure, Jigawa State, Nigeria to evaluate the influence of variety, seed form, and planting date, on the storability of potato (Solanum tuberosum L.) tubers. Treatments consisted of four potato varieties (Nicola, Bertita, Diamant, and Agria), two seed tuber forms (whole tuber and cut setts), and three planting dates of four weeks intervals (November, December, and January) factorially combined and laid in a split- split plot design, replicated three times. Characters evaluated were tuber percentage weight loss, sprout, and rotting during storage at 4, 8 and 12 weeks after harvest. Thirty tuber samples of healthy and marketable sizes were randomly selected for each treatment and spread in clean disinfected wooden crates of 30 x 30 x 10 cm in length, wide, and depth dimensions stored in a well-ventilated room, under ambient conditions. The containers were arranged in a completely randomized pattern and inspected fortnightly, over a period of 3 months. Observations on mean weight loss, sprouting, and rotted tubers in percentage were taken and recorded at 4-week intervals. Results revealed that a significant influence was on percentage tuber weight loss at 12WAS, sprout at 8WAS, and rot at both 8 and 12WAS where variety Diamant consistently produced more tuber weight loss, sprout, and rot than other varieties. Between the two seed forms, a significant influence was on percentage weight loss at 12WAS only, where cut tuber produced significantly more weight loss than whole tuber. Variation in planting date on the other hand, resulted in a significant difference in percentage tuber weight loss and sprout where December and January plantings produced more tuber weight loss than November planting, while November planting produced more percentage tuber sprout than December and January plantings that were at par with each other. Likewise, seasonal variation resulted in a significant difference in percentage tuber weight loss, sprout, and rot whereas 2015/16 consistently resulted in more percentage tuber weight loss, sprout, and rot than the other two seasons. Based on this research, Nicola and Agria planted as a whole tuber in November and December is recommended for farmers in the study area
Keywords: *Variety, sprout, storability, rot, weight loss, treatments*

INTRODUCTION

Potato (*Solanum tuberosum* L.) is one of the most important vegetable crops, constituting the fourth most important food crop in the world (FAOSTAT, 2013). The potato crop is graded as a high potential food security and cash crop because of its ability to provide a high yield of high-quality product per unit input with a shorter crop cycle (mostly < 120 days) compared to major cereal crops like maize (Adane *et al.*, 2010). Nutritionally, potato has the highest and most favorable protein-calorie ratio among the same class

of roots and tuber crops (Nganga, 1982). Also, the biological value of potato protein is very high and is equal in quality to egg and milk protein (Sikka and Kanzikwera, 1993). However, in spite of this immense importance and contribution towards the reduction of nutritional deficiency as well as poverty alleviation in the country, production, yield and utilization is constrained for some reasons. A number of productions constrain that account for such low yields and utilization have been identified. The major ones are unavailability and high cost of seed tubers, lack of well adapted cultivars, inappropriate agronomic practices, diseases, insect pests and inadequate storage (Bereke, 1994). Hijmans (2003) predicted yield losses globally for potato in the range of 18 to 32% without adaptation in production methods, or 9 to 18% without adaptation in terms of planting time and use of heat tolerant cultivars.
The overall potato seed quality is affected by purity, genetic quality, health, size, physical damage and physiological age. Differences in variety characteristics determine the suitability for the cutting of seed potatoes. It includes rotting of some varieties compared to others, the number and position of eyes, especially limited to the apical part of the tuber (Fienie, 2016). Lenka *et al.*, (2013) in Plateau State for example, reported that the crop is mainly cultivated by whole seed tubers in which the continuous use of seed tubers has been found to bring about degeneration of tubers and also reduced the quantity of production. For economic consideration, in Nigeria quality of seed tubers is a serious challenge because of inadequate storage facilities and adaptable cultivars which resulted in farmers inability to break even. In view of the afore mentioned reasons, research was therefore undertaken to evaluate the influence of variety, seed form and planting date, on storability of potato tubers after harvest in the study area.

MATERIALS AND METHODS

Study area

Field experiment was conducted during three dry seasons (between 2015 and 2018) at Kazaure, Jigawa state, located at latitude 12º 38’ 54.46’’N and longititude 8º 24’ 42.41’’E and situated at an altitude of 635m above sea level. The climate of the area is semi-arid, with mean annual rainfall of 600mm. The relative humidity in the study area ranges from 21-47% during the dry seasons, with mean annual temperature of 25.9^0C. The area is controlled by two trade winds, northeasterly from October to March, which is dry and brings harmattan, and southwesterly, from April to September, hot and humid and brings rain. The bulk of agricultural activities are undertaken by small scale subsistence level farmers, involving family labour mostly using manual tools, associated with high level of risk caused by draught, flood, pests and diseases. The soil type is sandy loam of Chad basin formation, and the major crops cultivated are cereals (millet, sorghum, cowpea e t c) during wet season and vegetables (tomato, pepper and onions) in the dry season (Anon, 2009).

Experimental design, treatments, data collection and analysis

The treatments consist of four potato varieties (Nicola, Bertita, Diamant and Agria), two seed tuber forms (whole tuber and cut setts) and three planting dates of four weeks intervals (November, December and January). The treatments were factorially combined and laid out in a split-split plot design with three replications. In the design of the experiment, the varieties were allocated to the main plot, seed tuber forms to the subplot, while planting date was assigned to the sub-sub plot. Planting was carried out at three different dates starting from 14^{th} November to 15^{th} January as per the treatment, in each season. During planting, each plot consisted of five rows with ten seeds planted per row, giving a total of fifty stands per plot. Fertilizer was used at the recommended rate of NPK 120-60-60, applied using (NPK 15:15:15) in two split doses with half of N and all the P and K during planting, the second dose applied at 4 weeks after planting using Urea 46%N. Weeds were controlled manually using hoe at 2 to 3times during each trial, as determined by the weed status. Harvesting was carried out manually by uprooting tubers from the ground using hoe. Characters considered were tuber percentage weight loss, sprout and rotting during storage at 4, 8 and 12 weeks after harvest. Thirty tuber samples of healthy and marketable sizes were randomly selected for each treatment and spread in clean disinfected wooden crates of 30 x 30 x 10 cm in length, wide and depth dimensions stored in a well-ventilated room, under ambient condition. The containers were arranged in a completely randomized pattern and inspected fortnightly, over a period of 3 months. Observations on mean weight loss, sprouting and rotted tubers in percentage were taken and recorded at 4 weeks interval. The data generated was pooled and subjected to combine analysis of variance (ANOVA), using GenStat software, Seventeenth Edition. The treatment means however, were separated for significant F value, using Duncan Multiple Range Test (DMRT) at 5% probability level.

RESULTS

Table1 presents the influence of variety, seed form and planting date on percentage weight loss, sprout and rotting of potato at 4, 8 and 12 weeks after storage in the study area. The result indicated that variation in variety resulted in a significant ($P \leq 0.05$) influence of percentage tuber weight loss at 12WAS, sprout at 8WAS and rot at both 8 and 12WAS where Diamant variety consistently produced more tuber weight loss, sprout and rot than other varieties. Between the two seed forms, significant influence was on percentage weight loss at 12WAS only where cut tuber produced significantly more weight loss than whole tuber. Variation in planting date on the other hand, resulted in a significant difference of percentage tuber weight loss at all samplings and sprout at 4 and12WAS where December and January planting dates produced more percentage tuber weight loss than November planting while November planting on the other hand produced more percentage tuber sprout than December and January plantings that were at par with each other. Seasonal variation also resulted in a significant difference of tuber weight loss, sprout and rot at all sampling periods except tuber weight loss at 8 and 12WAS. During the investigation, 2015/16 season consistently produced more tuber weight loss, sprout and rot than other two seasons.

DISCUSSIONS

Varietal differences resulted in a significant ($P \leq 0.05$) influence of percentage tuber weight loss at 12WAS, sprout at 8WAS and rot at both 8 and 12WAS where Diamant variety consistently produced more tuber weight loss, sprout and rot than other varieties. This supports the findings of Vander Zaag *et al*., (1990), Gogapale, (2012) and Muhammad, (2014) who reported significant influence of these attributes with variation in variety, they observed that cultivar differ in their dormant period, some are short dormant period while others are long. They also attributed the variation in tuber quality like heat tolerance, storability, cooking and processing quality to cultivar differences. Seed form follows the same pattern with cultivar, where the significant difference was at 12WAS only, during which cut tuber produced significantly more weight loss than whole tuber. Tindal (1989) reported that cut sett resulted in the removal of apical dominance which ensures more sprout/tuber, but this does not however apply to tuber quality during storage.

This result further affirms that quality attributes are not affected by agronomic practices but by genetic and environmental factors. Planting date and seasonal difference on the other hand, significantly influence percentage sprout of potato tuber at 8 and 12WAS as well as tuber percentage rot at all sampling periods respectively. This is attributed to variation in climatic condition obtained during the growth period. The significant influence could also be as a result of variation in environmental factors during the period of storage, especially high temperature which hastened tuber degeneration and deterioration. Hassanpanah *et al*., (2009) working on plating date effect on yield components of potato cultivars under Ardabil's climate in Iran reported that planting date, is very essential, therefore tuberization and tuber bulking should not coincide with unsuitable environmental conditions (heat, drought and etc.) with special attention to the growth period of a cultivar. They asserted that, if planting date was not regarded, not, only crop quality decreases but the secondary growth would also be created in tubers.

CONCLUSION

The results of this study revealed that among the varieties studied, Nicola recorded less weight loss, while Agria had less rot and sprout percentage during storage. But whole tuber produced less tuber weight loss, while November planting produced less tuber weight loss, compared to December and January planting dates that together produced tubers with lesser rotting and sprouting percentage under storage. Therefore, Nicola and Agria varieties planted as whole tuber in November and December is recommended for farmers in the study area for good storability quality attribute and more economic benefit.

ABSTRACT
Application of agro pesticides have significant impact on both beneficial and non-beneficial pests. It is important to develop organo pesticide with little or no side effect on the beneficial pest. Therefore, this study was carried in the year 2022 in Biotechnology Laboratory, Jigawa State Polytechnic to determine the influence of organo pesticide on the susceptibility and adaptability of weevil and grasshopper. Basic procedures were taken to produced organo- pesticide such as collection goat urine and ginger extract, sterilization, crushing, fermentation and storage at room temperature for 14 days. Each of the ten samples of bean weevil and grasshopper were subjected to the toxicity effect of organo-pesticide. Data collected were subjected to descriptive statistic such as percentage using Statistical Package for Social Sciences (SPSS). Results showed that bean weevils had 100% mortality rate followed by grasshopper with 60 percent. The extract had high effect to store pest (bean weevil) than field pest (grasshopper). Therefore, recommended that more studies should be carried out to with use of different plant and animal extracts for assessing the effectiveness of the bio-pesticide on several insects to reconfirmed the findings. ***Keywords:** Susceptibility, Adaptability, Weevil, Grasshopper, Influenced, Organopesticides*

INTRODUCTION

Human environment and Agricultural crops are under constant assault by insect pests, making the use of insecticides to have paramount importance to reduce losses (Wei *et al.,* 2018). Synthetic insecticides such as organophosphates are important and effective tools in modern crop management. However, they cause serious threats to the environment and to people. Humans come in contact with dangerous pesticides on food, in water and in the air near farms. Pesticide drift occurs when pesticide dust and spray travel through wind to places unexposed to pesticides. Almost 98 percent of sprayed pesticides do not reach their targets. They penetrate to groundwater, pollute streams and harm wildlife, including natural predators of the targeted pests. Older pesticides such as DDT killed bald eagle, birds, fish and even people (USEPA, 2023). Specialists representing various areas of the vast field of biology are contributing—entomologists, pathologists, geneticists, physiologists, biochemists, ecologists—all pouring their knowledge and their creative inspirations into the formation of a new science of biotic controls (USEPA, 2023). The perception that pesticides are harmful to human health and the environment has led to the implementation of more restrictive legislation dealing with allowable chemicals and residue levels. Other problems associated with excessive use of pesticides are the development of resistant strains (Cabanas *et al.,* 2009).

Exploring the potential to utilize the pesticidal properties of plants and animals has become a key focus of research in pest control. Some plants are known to contain bioactive metabolites, which show antifeedant, repellent and toxic effects on a wide range of insect pests (Kabrambam *et al.,* 2021). Many plants can protect themselves against insects by producing their own chemical defences that are toxic or repellent (Jessica Yactayo-Chang *et al.,* 2020). Bio-pesticides are naturally occurring substances from living organisms (natural enemies) or their products (microbial products, phyto-chemicals) or their by-products (semio-chemicals) that can control pest by nontoxic mechanisms (Salma and Jogen, 2011). Organization for Economic Co-operation and Development (2009), viewed bio-pesticides as manufactured mass produced agents derived from natural sources living micro-organisms and sold for use to control pests. According to Suman and Dikshit (2010), biopesticides encompass broad array of microbial pesticides, biochemicals obtained from micro-organisms and natural sources. Historically, biopesticides has been associated with the biological control and by implication, the manipulation of living organisms (Jitendra *et al.,* 2021). Biopesticides are usually inherently less harmful/toxic and cause less environmental load or pollutions. They are usually designed to only one specific pest or, in some cases, a few target pests as opposed to chemical that have a broad spectrum activity. Although the knockdown effect of biopesticide was proved to be delayed, and plus being costlier, it is reported that it reduced the number of application and are less prone to resistance. In recent decades, the focus on crop production have shift from yield to quality and safety produce.

Evidences suggest that biopesticide is an important component for promoting sustainable agriculture; hence it has gained lots of interest in the last decade particularly in view of the growing demands for organic foods (Emmanuel *et al.,* 2021). For a time in memorial, several biopesticide effect and efficiency have been assess by many scientist such as Salman *et al.* (2020) that tested the biological effects of a neem-based biopesticide on the repellency, mortality, oviposition, and development of Asian Citrus Psyllid (*Diaphorina citri*), Tang *et al.,* demonstrated that neem was effective in controlling the brown citrus aphid, *Toxoptera citricida* (Kirkaldy) and important vector of citrus tristeza virus (Halbert and Brown, 2023) used Garlic (*Zingiber officinale*) to produce a biopesticide that is naturally with fungicidal and pesticide properties that work effectively on controlling pests and makes an excellent economical, non-toxic biological pesticide for use in agriculture. Amuji *et al.,* (2012) investigated the effectiveness of ginger as a biocontrol method of controlling pests and insects on agricultural crops. Chemical made pesticides used in the farms are very toxic to the extent that the toxin tends to accumulate in the plant and translocated to different part of the plant such as seed which when consumed by human cause health effect. Constant damage to agricultural products is usually controlled by using chemicals that are toxic to even the insect which causes the damage. However, some biological agents are reported to possess certain pesticidal effects, hence this study aimed at determining pesticidal properties of crude garlic-goat urine extract crude on some selected insects.

MATERIALS AND METHOD

Description of the study area

The study was conducted in Dutse 11°42′04″ N, 9°20′31″ E. The rock city located in north western Nigeria. It is the capital city of Jigawa State and home to Federal University Dutse, Research Institute for Date Palm (Sub-Station) and State Polytechnic. The capital has an estimated population of 153,000 (2009), and total area of 7,382km^2 currently the largest city in Jigawa State. : Sulaiman *et al.,* 2018; Salami *et al.,* 2019). The climate of the city is classified as tropical and experiences two distinct seasons; the wet season which lasts from June to September with mean temperature of 31 °C but may linger until October, whereas the dry season extends from October to May (Zangina, 2015; Sulaiman *et al.,* 2018; Salami *et al.,* 2019). During the dry season, mean daily temperature ranges from 20 °C in the cooler months of October to February to 42°C during the hotter months of March to May. Annual rainfall ranges from 600 to 1 000 mm. Soil well known to be fertile ranging from sandy-loamy, pH ranges from 6.07-6.72, nitrogen content ranges from 0.63-1.64g/kg, phosphorus 6.25 to 12.04mg/kg and potassium ranges from 0.18-0.63cmol/kg respectively (Salami *et al.,* 2022; Aminu, 2021). The main vegetation type is Sudan savannah. As the state capital, during the last two decades, Dutse have faced a series of lands destruction in the name of urbanization including the construction of the first Airport in the state and other Estate. Raised in food and shelter needs in order to meet the demand of the increasing population of Dutse has also accelerated the used of herbicides in the farmlands, human settlements. Cash crops, such as potato, mango, peanut, bean, cotton, sugarcane, date and several types of vegetables, are produced in large quantities. Agricultural activities are not the major threat but the rate at which the farmers are using herbicides now in Dutse is highly alarming (Sulaiman *et al.,* 2018).

SAMPLE COLLECTION AND PREPARATION

The goat urine were collected from Jigawa State Polytechnic Bitanul garden and the ginger was bought from Dutse Ultra-Modern market. The plant was washed with clean water, blended and store in the clean container prior to use. Glass equipment's such as measuring cylinder, conical flask, and funnel were autoclaved at 121°C for 15min to achieve sterilization. About 50 ml of goat urine were measured using measuring cylinder and added into bottle container, 25gram of fresh ginger was weighed and grinded, then added into goat urine container and stored at room temperature for about 14days (2 weeks) for fermentation (Brooklyn Botanic Garden, 2000). The fermented mixture of goat urine and ginger were sieved to remove the residue. About 50ml of the biopesticide produced were then diluted with 50ml of water and carefully shake before spraying on insect/ pest of interest (Ellis *et al.,* 1992; Brooklyn Botanic Garden, 2000).

Biopesticide effect testing on the selected insect

Effect of the biopesticide produced were tested by spraying it on subject at the same concentration, and the mortality rate were observed. The biopesticide effect were found to be very effective due to the fact that, (goat urine and ginger) contain substances such as urea, sulphur and allicin that kill insects (Ellis *et al.*, 1992; Brooklyn Botanic Garden, 2000).

Data analysis

The data were analyzed using Statistical Package for Social Sciences (SPSS). Descriptive statistics such as: percentage.

RESULTS

Several steps, method and procedures were followed to obtain a compilation of the experiment by successful production of biopesticide from goat urine and ginger extract mixture which effectiveness were tested on various insects/ pest (Table 1). It was observed that, the mortality rate varies on the type of insect's pest tested. Total of 10 individuals of grasshopper and beans weevil were subjected to the test in order to determine the effectiveness of the produced biopesticide. The study found that, Beans weevils were more susceptible to the biopesticide with 100% mortality rate the followed grasshopper which had 60%.

Table 1: Showing the effect of Goat urine-ginger extract on selected insects

Type of insect		Total number	Mortality rate	Survivor	Percentage (%)
1,	Grasshopper	10	6	4	60%
2.	Beans weevil	10	10	0	100%

DISCUSSION

Biopesticides are now being recognized as growing components in the crop protection armoury. Key elements impacting future developments and acceptance include limited funding for research and development, limited shelf-life, high specificity (which can also be an advantage), limited persistence in the environment (in some instances also considered an advantage) and variable field performance (Leonard *et al.,* 2000). Many of these obstacles will be overcome as greater knowledge and experience of their use is incorporated into the selection and marketing of new products, thereby allowing companies to introduce improved products into global markets.

Results from this study proved that, goat urine-ginger extract possesses a high level of biopesticidal effect, based on the result in Table 1, it is enough to say that this is very good and working biopesticide. Results from the study are in agreement with the findings of some other literatures. The mortality rate of the insects treated with biopesticide could be due to toxic effects of the extract against the insects, this is in line with the Ellis *et al.* (1992); Brooklyn Botanic Garden (2000) that uses the extract as biopesticides.

No effect was reported from the use of prepared/produced biopesticide sample. The biopesticide was produced and tested effectively as required and has non-toxic and non-allergic effects to humans and other related animals. Environmentally, the production was pollution free and doesn't involve in any known toxic chemical reactions. The raw materials use for the production was entirely cheap and natural products. The study shows that, use of biopesticides is markedly safer for the environment and users, and more sustainable than the application of chemicals, their use as alternatives to chemical pesticides, especially as components in Integrated Pest Management (IPM) strategies, is of growing interest. The major advantage of the use of biopesticide for crop pest's management is environment safety along with their host specificity. Besides, the associated costs for the development and the registration of the biopesticide are comparatively lesser than that of the chemical pesticides.

CONCLUSION AND RECOMMENDATIONS

The biopesticide were successfully produced from goat urine-ginger extract; its effectiveness was determined on different pests. The results of the study have shown a promising pesticidal/insecticidal activity of goat urine-ginger extract in controlling pest/insects on both storage and treatment. The study believed that goat urine-ginger extract could replace the use of conventional synthetic chemical pesticide containing harmful chemicals as well as residue that may affect human and the environment. The study recommended the use of goat urine-ginger extract as biopesticides for the control of insect’s pests to both small scale and large scale farmers as an alternative to the issue of synthetic chemical looking at the fact that it’s environmentally friendly and healthier for both humans and animals. It can be used to protect several agricultural products from pest since it contains pesticidal properties, readily available, cheaper and less toxic to the immediate consumers. It is further recommended that; more researches should be carried out on assess the effectiveness of the biopesticide on several insects to reconfirmed the findings. Different other plant and animal parts should be used and produce more biopesticide of various kind to determine the most effective one in order to minimize the use of chemical pesticides.

ABSTRACT
The study was carried to determine the effect of seed treatment in sprouting and early seed shoot development of Queen palm (Syagrus romanzofiana). The experiment was carried out in Horticultural Technology Departmental project site of Federal College of Agriculture, Akure, Nigeria. Sixty seeds each of Queens Palm were collected from International Institute of Tropical Agriculture (IITA) Ibadan. The study involved the use of four (4) treatments and three (3) replicates. Data collection includes; Days to 50% emergence of seedlings, number of leaves per plant at 2 weeks interval, and plant height per plant at 2 weeks interval. The treatment combinations are Popped (PD), Depoped (DPD), Depoped and Washed (DPDW), Depoped and Washed and soaked for 24hrs (DPDWS) seeds. The result shows that number of leaves was significantly (P < 0.05) higher in DPD (Deppoded) at 16 WAP with the mean score of 2.444. Plant height was not significant (P< 0.05) with the treatment except at 12 and 20 weeks after planting (WAP) where DPDW have highest mean score of 28.78cm and 35.37cm respectively. The findings also show that DPD (Depoded) seed was more viable in early germination, therefore this study suggested that dormancy in queen's palm might arise from the hardness of the seed coat and Depoped (DPD) method of seed treatment is recommended for the propagation of queen palm.

INTRODUCTION

The longevity or ability to preserve seed viability is essential for the formation of a persistent soil seed bank (Thompson, 1997), which plays a decisive role in the adaptation of species to different environments (Baskin and Baskin, 2014). Because of the peculiarities in different habitats, the most accurate method of assessing seed longevity is to bury them in the ground and remove samples at certain time intervals to determine their viability (Baskin, and Baskin, 2006; 2014). *Syagrus romanzoffiana* (Cham.) Glassman (Arecaceae), popularly known as "queen palm" is a palm native to South America, and widely used as an ornamental plant in several other countries (Lorenzi, 1996). The species has potential for biodiesel production due to the high lipid content of the seeds, which can exceed 50% (Moreira *et al*., 2013). Additionally, *S. romanzoffiana* is able to grow in dry environments (Falasca *et al*., 2012) and shows abundant fruiting throughout the year (Genini *et al*., 2009) which represents an important advantage over other perennial oleaginous species with seasonal fruit production. These characteristics have stimulated discussions about the deployment of the species as a commercial crop, as raw material for biodiesel production (Falasca *et al*., 2012). Sensitivity to dehydration and susceptibility to chemical or microbial deterioration in the seeds of many palm species are factors that cause decreased viability after harvest (Broschat, 1994; Orozco-Segovia *et al*., 2003). It is generally recommended to immediately plant seeds while still fresh. However, storage of diaspores may be important both for managing propagation and for *ex situ* conservation programmes. Studies on embryo viability and vigour (Ribeiro *et al*., 2012) in stored seeds may contribute to the development of technologies for the production of seedlings, the propagation of the species and the storage of *S. romanzoffiana* seeds.

MATERIALS AND METHODS

The experiment was carried out in Horticultural Technology Departmental project site of Federal College of Agriculture, Akure. The climate of the area is tropical savanna wet with high temperatures and high humidity. The maximum temperature is 35ºC while the minimum temperature is 23ºC. The climate is characterized by two distinct seasons namely; rainy and dry seasons with an annual rainfall of 1100mm-1500mm. The vegetation of the area has been described as Southern guinea savanna. Sixty seeds each of Queen Palm were collected from International Institute of Tropical Agriculture (IITA) Ibadan. The experimental field was cleared using cutlass, raked and the existing vegetation were removed. The experimental field was marked with pegs and ropes to determine the accurate plot size. Soil samples were collected from various spots on the experimental plot at 0.15cm depth and bulked for analysis to ascertain the physico-chemical parameters of the soil. The experimental field was fenced with nets, partial shaded and polythene bag was used with the size 8 by 4 inches. The experiment was laid out in Completely Randomized Design (CRD)with four (4) treatments and three (3) replicates. This treatments combination is as follow: (i) Popped Seed (PD), (ii) Seed Depoped (DPD), (iii) Seed Depoped and Washed (DPDW), (iv) Seeds Depoped and Washed and soaked for 24hrs (DPDWS). Data collection includes; Days to 50% sprouting, Number of leaves per plant, and Plant height per plant, at 2 weeks interval of collection. Data collected in this study was subjected to Analysis of Variance (ANOVA).

RESULTS

Effects of Seed Treatment on Number of Leaves

Seed treatment had significant ($P < 0.05$) effect on number of leaves of Queen palm (Table 1). Number of leaves was significantly ($P < 0.05$) higher in DPD at 16 WAP with the mean score of 2.444. Though at 12, 14, 18, 20, 22, 24, 26, 28 and 30 WAP, PD, DPD, DPDW and DPDWS were not significantly ($P< 0.05$) different in their effects on number of leaves of Queen palm, DPD slightly produced the highest number of leaves.

Effect of Treatment on Plant Height of Queen Palm

Plant height was not significant ($P< 0.05$) with the treatment except at 12 and 20 weeks after planting (WAP) where DPDW have highest mean score of 28.78 and 35.37cm respectively. In spite of the non-significant difference, At 10 weeks after planting, t DPDW recorded the tallest plant (26.37cm) at 10 WAP, same trend was observed at 14, 16, and 18 WAP where DPDW has the highest mean score of 28.56, 33.02, and 33.46 respectively. In a related development, at 22, 24, 26, and 28 WAP, the plant height was not significant ($P<0.05$) however, DPDW has the highest mean score of 39.57, 40.19, 42.84, and 46.91 respectively. Hile, at 30 WAP, the plant height was significant ($P<0.05$) with the treatment where PD has highest mean score of 53.12.

DISCUSSION

This study demonstrates the effectiveness of various methods of breaking dormancy on *S. romanzoffiana* seeds. It also shows how seeds responded to the different treatment combinations. Results indicated that seed dormancy in *S. romanzoffiana* arises from the hardiness of the seed coat. This finding is similar to that of Okunlola *et al.* (2011) who reported that seed dormancy in *Parkia biglobosa* was associated with the hardness of the seed coat. The increase in the germination rate of the Queens Palm seeds could be attributed to the removal of the cuticle and softening of the seed coat by the different methods tested for breaking seed dormancy of *S. romanzoffiana*. Treatment of seeds with Popped Seed was found to induce the highest germination rate compared to other treatments. This could largely be attributed to the influence of the acid that acted on the seed coat. This also may have penetrated the seed coat and inhibited the chemical compounds causing the dormancy. This observation concurs with other studies (Purohit, 2015). Similarly, in overall, this study suggests that the reason for the high germination rate in water might be as a result of the action of the hot water on the seed coat and also on the chemical constituents.
Further possible explanation for the high germination rate in hot water compared to the other treatments was likely due to the high temperature of the hot water. This observation is in line with (Dewir e*t al.*

(2011) who observed hot water increased the rate of germination by its action on the seed coat, consequently breaking down the bonds between the chemical compounds in the seed coat responsible for causing dormancy. The pronounced variation observed in the number of leaves revealed the genotypic differences among the accessions which were evident in the phenotypic expression. Hanane and Halima (2020) noted that traits related to vegetative and reproductive organs could be a useful tool to assess phenotypic diversity and are therefore, used as tools for characterisation of plant species. Salem *et al.* (2008), reported that morphological traits such as plant height, length of petiole, girth of plant, length and grouping of spines, fruit and leaves contain quantitative markers used for identification, description, differentiation and characterisation of queen's palm cultivars. Differences were observed among the accessions in all the morphological parameters observed in this study. This is in line with the report of Djerouni *et al.* (2015), who noted that vegetative characteristics could be used to differentiate queens palm varieties.

CONCLUSION

Queen's palm is one of the most popular palms for commercial and home landscape. This fast-growing palm is used to line street or sidewalks or is often planted in clusters for fast structure and interest. Queen palm is able to grow in dry environments and shows abundant fruiting throughout the year which represents an important advantage over other perennial oleaginous species with seasonal fruit production. The findings of this study indicated that dormancy in queen's palm arises from the hardness of the seed coat. Thus, the need to overcome it is critical to aid water and gas exchange to enhance the rate of germination of the queen's palm seed. It is recommended that Depoped (DPD) method of seed treatment is ideal for the propagation of queen's palm.

EFFECT OF POULTRY MANURE RATES ON GROWTH, YIELD AND NUTRIENT COMPOSITION OF CARROT (*Daucus Carota*) IN KABBA

Etukudo, O. O and Ogundare, S. K
College of Agriculture, Division of Agricultural Colleges, Ahmadu Bello University, Kabba, Kogi State, Nigeria

Corresponding author: omololaetuk@gmail.com

ABSTRACT
The experiment conducted at the College of Agriculture, Kabba, during the 2022 cropping season aimed to assess the impact of varying poultry manure application rates on the growth, yield, and nutritional attributes of carrots. Employing a completely randomized design with five replicates, the study applied seven different rates of poultry manure, ranging from 0 to 12 t/ha. Observations encompassed various parameters such as plant height, leaf count, stem girth, root length, root diameter, fresh and dry root weight, root weight per plant, yield, and nutrient composition. The results of the analysis of variance revealed intriguing findings. At ten weeks after transplanting, the application of 12 t/ha of poultry manure resulted in the tallest plants, while 8 t/ha of PM fostered greater leaf production. The widest stems were observed in plants treated with 12 t/ha of PM, akin to those treated with 10 t/ha. The most extensive roots were recorded for the 6 t/ha treatment, on par with 2, 4, 8, 10, and 12 t/ha. Furthermore, the highest fresh root weight, dry root weight, root weight per plant, and yield were achieved with 10 t/ha of PM. Surprisingly, the application of poultry manure did not significantly affect the proximate traits assessed. In conclusion, the study recommends the use of 10 t/ha of poultry manure to optimise carrot yield for growers in the region.
***Keywords**: carrot, poultry manure, growth, yield.*

INTRODUCTION

Carrot (*Daucus carrota* L.) is one of the most important root vegetables classified under the family Apiaceae (Fikadu-Lebeta and Refisa-Jebessa, 2019). It ranked third among the succulent vegetables in world production (Yamaguchi, 1983). The edible roots of carrots contain water, protein, ash, vitamins,and minerals (Norman, 1992). Carrot is usually cultivated as an annual crop in the tropics, like Nigeria (De Lannoy, 2001). The crop requires a deep and well-drained loamy soil that is moderately acidic and high in organic matter (Yayock *et al*., 1988). Carrot contains carotene, thiamine, and riboflavin (Pant and Manandhar, 2007), as it enhances resistance against blood, eye, and other human diseases (Pant and Manandhar, 2007; Appiah *et al*., 2015). The crop is beneficial to resource-poor farmers because it is a short-duration crop and higher yields can be obtained per unit area (Ahmad *et al.,* 2005). However, low yields were reported in Nigeria by Sarkindiya and Yakubu (2006). The major reason for low yields is attributed to low soil fertility status. In order to obtain high and sustainable carrot yields, good soil fertility and constant growth are required to facilitate the production and translocation of carbohydrates from leaves to roots. The key limiting factors in crop growth, development, and yield are nitrogen, phosphorous, potassium, and water. In most cases, carrot growers use chemical fertilisers as the major supply of nutrients to attain higher growth and yield (Hochmuth *et al*., 1999; Amjad *et al*., 2005). Continuous application of synthetic fertiliser may lead to soil acidity, human health problems, and soil degradation because it releases nutrients at a faster rate. The increasing costs of synthetic fertilisers have made them generally unaffordable to most resource-poor, small-scale growers.
Organic manure can serve as an alternative to mineral fertilisers. Application of manure supplies the required nutrients, improves soil structure, water holding capacity, porosity, bulk density, moisture retention, increases microbial population, and maintains crop quality (Agbede *et al*., 2017). Poultry

manure (PM) is a good source of nutrients for plants such as carrots (Kankamet et *al*., 2014; Habimana et *al.,* 2014). There has been a continuous use of PM to fertilise crops by some farmers in Nigeria with no or limited documentation on performance. In Nigeria, proper disposal of poultry waste is a challenge for poultry farmers (Agbede and Adekiya, 2011), and its use in carrot production could be a solution. The objective of the study is to determine the effect of poultry manure rates on the growth, yield, and nutrient composition of carrots (*Daucuscarota*).

MATERIALS AND METHODS

The experiment was carried out in the College of Agriculture Kabba, located at a latitude of 7^0 51N and a longitude of 6^0 04E. It has an annual rainfall of 1,350 mm, an average annual temperature of 30^0 C, annual total number of sunshine hours of about 2,000 hours, a daily sunshine of about 5 hours, and a mean annual radiation of about 139Kcal/cm$^{2/}$year. The vegetation in the area is dominated by tall grasses and shrubs. The area is known for the production of arable crops such as maize, cassava, cowpea, yam, sorghum, and sesame. Nursery beds measuring 2m long and 1.2m wide were prepared. Seeds were sown thinly in rows. Seeds were nursed in March and transplanted in April 2022. The seed beds were watered and covered with mulching materials after sowing. After seed germination, the mulch materials were carefully removed and placed under shade, which was constructed with palm fronds to protect the young seedlings against harsh weather. The seedlings were watered until they reached the transplanting stage.

The experiment was laid out using a complete randomised design (CRD). Each treatment was replicated five times. Treatments included: T1 = 2 t/ha of poultry manure, T2 =4 t/ha of poultry manure, T3 = 6 t/ha of poultry manure, T4 = 8 t/ha of poultry manure, T5 = 10 t/ha of poultry manure, T6 = 12 t/ha of poultry manure, and T7 = no poultry manure (control). The soil was collected, air dried, and thoroughly mixed to ensure homogeneity. Therefore, 20kg of the soil sample was weighted into a polyethylene bag containing the pre-weighted animal manure, and both were thoroughly mixed to ensure uniformity of the treatment. Carrot seeds were obtained from the Research Institute (NIHORT) in Ibadan. The seeds were raised in the nursery before being transplanted to the pot five weeks after planting. The site was manually cleared with cutlass, and polyethylene bags were prepared and filled with appropriate substrates. Weeding was done manually at a 3-week interval.

A soil sample was taken from 0 to 15cm and bulked to have a composite sample, which was analysed for chemical and physical properties. The nutrient content of the poultry manure was analysed in the laboratory. Karate was used to control insect pests on the field. Data were collected on plant height (cm), number of leaves, stem girth (cm), root length (cm), root diameter (cm), fresh and dry root weight (g), root weight per plant (g), yield, and nutrient composition of carrot. All the data collected were subjected to analysis of variance (ANOVA) using the GenStat statistical package (GenStat, 2007). Means were separated using Duncan's multiple ranges at a 5% level of probability.

RESULTS AND DISCUSSION

The result of the properties of the soil is presented in Table 1a. The soil is rich in nutrients enough to support the growth of carrots. It has a high porosity, which suggests that the soil is free of iron concretions. The texture of the soil is sand clay loam and has a pH of 5.32 and a total nitrogen content of 0.27%. Table 1b indicates that the organic materials used contain enough nutrients for the growth and development of carrots. The result of different rates of poultry manure on the plant height of carrots is presented in Table 2. The result shows a significant ($p < 0.05$) difference in the plant height of carrots at 2, 4, 6, 8, and 10 weeks after transplanting. The results indicated that all plants grown in pots with poultry manure, irrespective of the rate of application, produced carrots taller than the control. This implies that the application of poultry manure is desirable in carrot production. Poultry manure, in particular, has been linked with a reduction in soil acidity apart from soil nutrient enrichment (Olatunji and Oboh, 2012; Sunassee, 2001). In a study by Parraga (1995), increased vegetative growth was attributed to the increased nitrogen content of the soil due to the addition of PM. This confirms White's (1992) report that organic manure improved soil structure and maintained uniform soil moisture and nutrient levels, which resulted

in root growth. An increase in poultry manure rates resulted in an increase in plant height. Among the organic manure-treated pots, the application of 12 t/ha of PM recorded the tallest plant at 10 weeks after transplanting. This was significantly better than all the other treated pots. The result obtained in this study may be linked to high nitrogen levels that facilitate the growth and development of foliage parts of the plant. This finding is in line with the findings of Mehediet et al. *(2001),* who stated that application of the highest rate of cow dung at 20 t/ha increased the growth parameters of carrot. Plants grown without poultry manure application (control) recorded the shortest plant at 10 weeks after transplanting.
Table 3 presents the effect of poultry manure rates on the number of carrot leaves at 2, 4, 6, 8, and 10 weeks after transplanting. Significant ($p < 0.05$) differences were observed in the number of carrot leaves at 2, 4, 6, 8, and 10 weeks after transplanting. The result indicated that all pots with poultry manure had more leaves compared to the plants that grew in the control. Application of 8 t/ha of poultry manure consistently produces more leaves than other rates used. At 10 weeks after transplanting, pots with 8 t/ha of PM produce 12 leaves. Leaves produced in pots with 4, 6, 10, and 12 t/ha of PM were similar. All these were significantly better than plants treated with 2 t/ha of PM. However, the least number of leaves was observed in the pot with the control (8.33 leaves). The decline in the number of leaves obtained above 8 t/ha of PM implies that a sufficient amount of nutrient elements was supplied by this rate. When optimum nutrients are supplied, it results in the production of high-quality and better-nutritional plants (Rice *et al.,* 1994; Baiyeri *et al.,* 2009). Adebayo *et al.* (2011) reported that when manure is available in adequate quantity, plants tend to grow to their optimal potential.
The effect of different rates of poultry manure on the stem girth of carrots is presented in Table 4. A significant ($p < 0.05$) difference occurred in the stem-girth carrots due to the different rate of poultry manure used, except at 2 weeks after transplanting. At 10 weeks after transplanting, the pot with 12 t/ha of PM recorded the thickest stem, followed by the pot with 10 t/ha of PM. The ability of 12 t/ha of PM to increase the stem girth of carrots could be attributed to the supply of adequate nutrients to the plant (Crosson, 1995). Pots with 2, 4, 6, and 8 t/ha of PM produced similar stem girth, which was significantly inferior to pots with 10 t/ha and 12 t/ha. The control pot recorded the thinnest plant in this experiment. The inability of 0 t/ha to produce the thickest stem may be attributed to a nutrient deficit in the soil.
The effect of different rates of poultry manure on the root character of carrots is presented in Table 5. Similar root length and root diameter occurred in all the pots with poultry manure, and all these were significantly better than the control. Root length and root diameter in the pot with poultry manure ranged between 18.80 and 21.09 and 4.74-6.41 cm, respectively. The result obtained in this current study can be linked to the release of nutrients that led to an increase in root length and root diameter. A similar result was reported by Kankam *et al.* (2014) in carrot.
The effect of different rates of poultry manure on the fresh weight, dry shoot weight,root weight, and root yield (t/ha) of carrots is presented in Tables 6 and 7. An increase in the rate of poultry manure resulted in a decrease in all the yield traits assessed. Plants in pots that received 10 t/ha of PM recorded the heaviest fresh and dry root weight and the highest root weight per plant and yield (t/ha) compared to others. The least was obtained in plants that grew in the control. The result obtained in this present study could be attributed to the enhancement of soil fertility status by 10 t/ha of PM, which improved carrot yield. Application of 10 t/ha of cattle manure improved the growth and yield of carrots, as reported by Daba*et al.* (2018), which was in agreement with our findings. Mazed*et al.* (2015) stated that the maximum root fresh weight of carrot was recorded from plants that received 25 t/ha of cow dung application, which contradicts our findings. Table 8 presents the effect of poultry manure rates on the nutrient composition of carrots. The result indicated that there was no significant ($p > 0.05$) difference in the nutrient composition of the carrot.

CONCLUSION

From the results obtained, it is evident that plants that received 10 t/ha (60g) had better performance in terms of growth and yield of carrot. Therefore, carrot growers should apply 10 t/ha of poultry manure for optimum production.

ABSTRACT

The study examined the perceptions of horticultural crop farmers towards access to market and commercialization. Data for the study were collected with a well-structured questionnaire from a cross-section of randomly selected 250 (125 maize farmers, and 125 okra farmers) respondents. The objective was achieved using Likert scale rating. Farmer's perception of market access and commercialization which was capture in five points Likert scale had a grand mean of 3.33 (maize), and 3.24 (okra) to imply that the farmers have a positive perception of market access and commercialization. The study recommends that governmental and financial institutions, especially the Agricultural Credit Schemes should be strengthened to provide soft loans to horticultural crops farmers at a very low interest rate.

Keywords: *Commercialization, determinants, horticulture, perception.*

INTRODUCTION

Due to the dependence of a large number of South-easterners on agriculture for their livelihood, the State Governments have made the development of the agricultural sector a top priority. One area identified for accelerated growth is the development of high-value crops such as horticultural crops (Ogbe, 2019). Commercialization of horticultural crops in South-East Nigeria is an essential pathway towards economic growth and sustainability (Enete & Ani 2020). However, adequate information on the perception of farmers on the marketing and commercialization of the business is lacking (Osuafor, Effiong & Ude, 2021). Most horticultural farmers in South-east are subsistence farmers who mainly produce for self-consumption; only selling the small surplus they have (Obi, Pote & Chianu, 2020).

Mayong et al. (2016) explained horticultural crop commercialization to mean the scaling up agricultural production from subsistence level to become market based. According to them, commercialization is characterized by expansion in sales of output which raises cash earnings of small-scale horticultural crop enterprises. To bring about commercialization, the unit of output can be increased, value addition can be raised, or both carried out, and there can be production for domestic and foreign markets. However, commercialization is dependent upon whether input and output markets are available. In Nigeria, the last one and a half decades have seen the government striving to encourage horticultural farmers to shift from subsistence to market-oriented production. Efforts have been put on intensification of the production systems, farmer cooperative promotion, and enhancement of farmers' access to markets (Komarek, 2020). As a result, increase in the commercialization and access to market for horticultural crops such as maize and okra is encouraged. Hence this study. The objective of the study was to examine the perceptions of horticultural crop farmers towards access to market and commercialization.

MATERIALS & METHODS

The study was carried out in South-East Nigeria. South-East Nigeria comprises of five states viz: Enugu State, Abia State, Ebonyi State, Imo State and Anambra State. Multistage, purposive and random sampling methods were used to select 3 States, 15 Local Government Areas (LGAs), 150 maize farmers and 150 okra farmers for the study. Data were collected from primary source using questionnaire administered to the respondents by personal interview. Out of the 300 filled questionnaires, 50 were wrongly filed and were dropped. Hence, 250 questionnaires were used for the analysis. The objective was actualized using Likert-scale rating techniques.

RESULTS AND DISCUSSIONS

Perceptions of Horticultural Crops Farmers towards Access to Market and Commercialization

The result of the horticultural crop farmers on their perception towards access to market and commercialization in Southeast Nigeria is presented in Table 1 (maize) and Table 2 (okra). The grand mean of 3.33 (maize), and 3.24 (okra) indicates that the farmers have a positive perception of market access and commercialization. Those in agreement with maize farmers are: there is a high competition in the market (3.82), access to market require more knowledge and competitiveness (3.82), value of agricultural inputs sourced from the market improved (3.92), gross agricultural product improved (3.92), and value adding to the agricultural produce has improved (3.85). On the other hand, those that agree with the okra farmers are: market access create conflict among participants (3.96), value of agriculture produce improve (3.73), value of agricultural sales to the market improved (4.02), value of agricultural inputs sourced from the market improved (4.19), gross agricultural product improved (4.11), and value adding to the agricultural produce has improved (4.20) among others.

CONCLUSION

Horticultural crop farmers have a positive perception of market access and commercialization. Based on the findings, farmers should be encouraged to get involved in the production and marketing of the crops. Also, soft loans should be given to horticultural crops farmers at a very low interest rate.

ABSTRACT
A field experiment was carried out during the 2017/2018 dry season at Samaru College of Agriculture, Ahmadu Bello University, Zaria to study the effect of potassium and irrigation interval on the growth and yield of tomato (Lycopersicon esculentus L.). The treatment consisted four levels of potassium (0, 20, 40 and 60 kg K_20 ha^{-1}) and two levels of irrigation (3 and 5 days interval), eight treatments arranged in factorial combinations and laid out in a Randomized Complete Block Design (RCBD) replicated three times. The results showed that application of potassium had no significant effect on growth parameters except number of leaves at 9WAT, where 40kg K_20 ha^{-1} produced significantly more number of leaves though not statistically different from 0 and 60 kg K_20 ha^{-1}. Irrigation interval did not also result in a significant effect of growth parameters except number of leaves at 9WAT, where 3 days interval produced significantly a greater number of leaves than 5 days interval. The result also indicated that potassium had no significant effect on all yield parameters, but 0 kg K_20 ha^{-1} resulted in a slightly increased yield parameters of the crop. Irrigation had no significant yield components too, although irrigation at 3days interval resulted in a slightly higher yield of tomato. The interactions on growth parameters showed no significant effect. Also interaction on yield parameters showed no significant effect except on number of non marketable fruits and weight of non marketable fruits hectare^{-1}.

INTRODUCTION

Tomato (*Lycopersicon lycopersicum* L. Krast) is one of the most important vegetable crops grown throughout the world field and greenhouse conditions (Kaloo, 1986). In terms of human health, tomato is a major component in the daily diet in many countries, and constitutes an important source of minerals, vitamins and antioxidant (Grierson and Kader, 1986). Tomato can be produced in both rainy and dry seasons. More importantly, it thrives well under irrigation in the northern part of Nigeria. This is because, the incidence of pest and diseases are low during this period. The commonly cultivated varieties in Nigeria are those with a determinate growth habit. Tomato belongs to the family *solanaceae* and it is believed to have originated in the coastal strip of western South America, from the equator to latitude of about 30^0 South. Indeterminate and determinate plant growth are characteristic of this family, where the former produce three nodes between each inflorescence with the later having fewer than three nodes on the stem, terminating in an inflorescence (Jones,1999). It possibly got to Asia in the 15th century from Spain. Tomato was taken across the Pacific Ocean to the Philippines and was found in the eastern Malaysia after 1650. It was introduced first to the Italy in the middle of the 16th century. Tomato was found in the united state towards the end of the 18th century. It must have spread to china, Japan, India and so on through their commercial activities with the Philippines.

Tomato got to Africa possibly through the British, Dutch, Greeks, Portuguese and French who colonized this part of the world. At this period, it was only cultivated on a small scale in the tropics except for Central America, until the end of the 19th century (Jones 1999). Tomato can grow on a wide range of climate conditions of both tropic and sub-tropics. It thrives well on a well drained fertile soil which is fairly deep and rich in organic matter especially, but not water-logged. The field should be free from nematodes and stubborn perennial weeds. The crop require abundant sunshine and cool weather of about 20 - 27˚C day temperature and 15 -21˚C night temperature. High humidity and temperature are intolerable especially at seedling stage (Kaur *et al,* 2005).

It is important to mention too, that, some cultivars show increased growth rate with alternating high day and low night temperature, while others do not. For instance, stem length increase with day temperature and leaf area increases with night temperature. Also, with low light and high temperature, fruit development is arrested. (Kaur *et al,* 2005). Tomato (*Lycopersicon esculentus* L.) is the second most important vegetable crop next to potato. Present world production is about 100million tons fresh produced on 3.7 million hectares. Tomato production has been reported for 144 countries (FAOSTAT, 2004), the major country being china in both hectares of harvested production (1,255,100 hectares) and weight of fruit produced (30,102,040 tons). The two leading countries in fruit, yield per hectare are the Netherland (4,961,539 kg ha^{-1}) and Belgium (4,166,667 kg ha^{-1}). The top five (5) leading fruit producing countries are the United State, China, Turkey, Italy and India (FAOSTAT, 2004). The crop is mainly cultivated under the rain in the tropic and sub-tropical regions but almost on the field in the temperate regions with the aid of irrigation. Tomato production in Africa, was estimated that about 9 million tons on 443,000 hectares of land are produced annually, while in Nigeria 680,000 tons on 22,000 hectares are produced yearly (FAOSTAT, 2004). In Nigeria, tomato is produced both in the rainy and dry season but it performs best under irrigation in the dry season (in the Northern part of the country), where pest and disease incidence is minimal.

Low yield in production of tomatoes in Nigeria has always been attributed to low level of fertilizer in the soil. Most of the Nigeria tomato farmers had the wrong perception that tomato crop does not require fertilizer and irrigation application during dry season for optimum performance. This is seriously affecting the crop yield per hectare as well as the farmer income. Also the country revenue on tomato production is negatively affected. It is therefore in view of the above mentioned problem that this study was proposed to investigate the effect of potassium and irrigation application in the study area. The objective of this study is to determine the effect of potassium and irrigation interval on the growth and yield of tomato production in Samaru, Zaria.

MATERIALS AND METHODS

Experimental site

The experiment was conducted in the field under irrigation during the 2017/2018 dry season at the agronomy section of Samaru College of Agriculture, Ahmadu Bello University, Zaria. Samaru is located at the northern guinea savanna ecological zone of Nigeria at latitude 11˚11'N and longitude 7˚38'E, 680 meter above sea level. Samaru experience a mean annual rainfall of 1080 mm and daily temperature range of 21˚C - 36˚C. The texture of soil after analysis was found to be sandy loam. The weather condition of the environment was fairly good at the beginning of the experiment but became harsh at the later phase of the crops life cycle.

Treatments and experimental design

The treatment consisted of four levels of potassium (0, 20, 40 or 60kgK_2O/ha-^{1}) and two levels of irrigation (3 or 5days interval) making a total of Eight treatments arranged in a factorial combinations and laid out in a randomized complete block design (RCBD) and replicated three times. Experimental area was 6.5m × 15m = 97.5m^2, consisting of 24 plots each plot size was 1.8m × 1.35m =2.43m^2. The land was ploughed and harrowed to a fine till on 23rd December, 2012 to improve the structure and water holding capacity, reduce soil borne pests and diseases by exposing the soil to hot sun and also to remove weeds. It further encourages root growth, breaking of clods and removing crop residues to level the land and a raised bed was constructed by making outer edge of the bed by a garden line to ensure that all side of beds are firmly beaten with the help of hoe to prevent side from being washed away by water. The tomato variety used was the determinate type with the line number UC 82 B obtained from genuine agrochemical dealer in Samaru, Zaria. Six weeks old tomato seedling were transplanted, one plant per hole on the 5th February, 2013.

Two levels of irrigation were imposed, with one set receiving water once every three days and the second, once every five days throughout the period of the experiment, beginning from one week after transplanting. Nitrogen (13.5kg/ha) were applied at two split dose to all the plots using urea (110%N), first at transplanting and at 4 weeks after transplanting at each application. Phosphorus and potassium was applied as single super phosphate (45% p_20_5) and muriate of potash (45% k_20) as shown: K_1 = 0.0g Mop Plot^{-1} = (0 kg k_20 ha^{-1}), K_2 = 4.86g Mop Plot^{-1} = (20 kg k_20 ha^{-1}), K_3 = 9.72g Mop Plot^{-1} = (40 kg k_20 ha^{-1}), K_4 = 14.58g Mop Plot^{-1} = (60 kg k_20 ha^{-1}). The phosphorus and potassium were applied along with nitrogen as basal application after transplanting. The fruits were harvested manually at maturity; that is, the period at which the fruits were almost reddish in color.

Data collection

Plant height (cm), number of branches plant^{-1}, number of leaves plant^{-1}, number of flower plant^{-1}, number of fruits plant^{-1}, fruit fresh weight plant^{-1} (kg). The data collected were subjected to statistical analysis of variance using Gen Stat. Significant differences between the treatment means were compared using Duncan Multiple Range Test (DMRT) in accordance with Gomez and Gomez (1984).

RESULTS AND DISCUSSION

Effect of potassium and irrigation interval on growth parameters

Table 1 shows the effect of irrigation and potassium on plant height at 3, 6 and 9weeks after transplanting, respectively. There was no significant difference of irrigation on plant height among all the irrigation interval, however, at 3days of irrigation was slightly higher than 5days but, at 6WAT and 9WAT, 5days irrigation was higher. The non significant difference observed on plant height by varying irrigation period between 3 and 5days indicated that irrigating between 3-5days is adequate for normal plant growth, meaning that at 3 or 5days water was supplied at the right time. This contradicts the works of Fawusi (1980), who reported that irrigation has a positive effect on all growth components of tomato if sufficiently supplies in the right amount and time. This is probably because the gap was not wide enough for the effect to be manifested. There was no significant difference of potassium application on plant height among all the treatments, however, at 3WAT; 0 kg K_20 ha^{-1} gave taller plants while, and 40 kg K_20 ha^{-1} had the shortest plant height. At 9WAT, 60 kg K_20 ha^{-1} produced taller plants than 0 kg K_20 ha^{-1} and 40 kg K_20 ha^{-1}. The non significant difference on potassium at 0, 20, 40 and 60 kg K_20 ha^{-1} rates respectively in plant height supports the findings of Angelov (2002), who reported that potassium had no significant effect on the vegetative growth of the cultivar used. The interaction of potassium and irrigation frequency produced no significant effect on plant height.

Table 1 shows the effect of irrigation and potassium at different rates on number of leaves plant^{-1}. There was no significant difference of irrigation was observed except at 9 weeks after transplanting. Irrigating at 3days had the maximum number of leaves plant^{-1} than 5days of irrigation. At 9weeks after transplanting however, there was a significant difference between the two treatments. The significant difference observed at 9WAT between the two irrigation intervals was because at that period the plants matured enough and water requirement was more continent. This however supports the findings of Hernamdo and Orihuel (2004), who reported that number of leaves were significantly affected by irrigation regime, they however noted that the effect gradually decrease with decreasing irrigation rate. There was significant difference of potassium on number of leaves plant^{-1}, at all sampling periods but at 3 and 6WAS 0 kg K_20 ha^{-1} produced more number of leaves than other treatments, at 9WAT, though 40 kg K_20 ha^{-1} gave maximum result beyond which any additional potassium resulted in no increase on number of leaves. This result indicated that potassium is not a limiting factor on number of leaves especially at initial plant growth. The application of potassium was observed to have a significant effect on number of leaves plant^{-1} at 3 and 6WAT, though very inconsistent, at 3WAT the control was significantly higher, while at 6WAT, 40 kg K_20 ha^{-1} gave significantly higher number of leaves. The result showed that at 3WAT the plants were not mature enough. This closely agrees with Kaziev and Tursumetor (2006) who reported that growth and weight of tomato plant increased with increases in potassium application rate of 100 kg ha^{-1}

only in additional to N and P dressing, but a further rise to 150 kg K_20 ha^{-1} had no additional benefit. Interactions between irrigation and potassium rate were not significant at all the stages of growth.

Table 1 shows the effect irrigation and potassium on growth parameters on 50% flowering, fruiting and maturity of tomato. There was no significant difference on irrigation at 50% flowering, fruiting and maturity on tomato, however, 3 days of irrigation resulted in reduced days to 50% flowering and 50% fruiting however, 3days of irrigation resulted in delayed maturity. This result supports the works of Kwapata (1991), who reported that flower initiation and opening as well as number of fruit $plant^{-1}$ were significantly less in relatively wet soil moisture treatment. There was no significant difference of potassium at 50% flowering, fruiting and maturity. 0 kg K_20 ha^{-1} resulted in a slightly delayed 50% flowering, while 60 kg K_20 ha^{-1} resulted in delayed fruiting and maturity. This result follows the works of Sobuo *et al.* (1997),who reported that the effect of potassium on number of flowers $plant^{-1}$, fruit number $plant^{-1}$ were all observed at varying degrees by different workers depending on the soil nutrient status with respect to potassium in the soil. The interactions of potassium and irrigation did not result in a significant effect of 50% flowering, fruiting and maturity.

Effect of potassium and irrigation interval on yield parameters

Table 2 shows the effect of irrigation and potassium on number of fruits $plot^{-1}$, fruit yield $plot^{-1}$, weight of fruit $hectare^{-1}$ and fruit yield $hectare^{-1}$. Irrigation did not result in a significant difference of number of fruit $plot^{-1}$, yield of fruit $plot^{-1}$, fruit yield $hectare^{-1}$, and weight of fruit $hectare^{-1}$. Though, 3days of irrigation gave the higher yield compared to 5days of irrigation. This observations support the findings of Amico *et al*. (1985), who reported that the highest fruits $plant^{-1}$ was obtained with germination of 60% and fruiting at 80%, indicating that tomato is not very exigent on water but its productivity depends rather on water availability during certain stages of the crops' cycle. Irrigating at 3 and 5days indicated that water was supplied at the right time and amount which had positive effect on yield components of the crop. There was also no significant difference of potassium on number of fruit $plot^{-1}$, yield of fruit $plot^{-1}$, weight of fruit $hectare^{-1}$ and fruit yield $hectare^{-1}$. Though, 0 kg K_20 ha^{-1} had the maximum yield on number of fruits $plot^{-1}$, yield of fruits $plot^{-1}$ and weight per hectare while 40 kg k_20 ha^{-1} has the minimum yield on number of fruit per plot, yield per plot and weight $hectare^{-1}$. Potassium application did not show any significant effect on fruit yield and yield components. In this study, lack of significant effect could be due to its non significant effect on growth components or probably the low level of nitrogen in the soil (0.35) which normally complimented the uptake of other nutrients and could not trigger any significant response on yield. But, Matev (1995) reported that potassium had more significant effect at the later phase in the life cycle of tomato especially the reproductive phase.

Table 2 shows the marketable and non- marketable fruit $hectare^{-1}$ with the influence of irrigation and potassium at different application rates. There was no significant difference due to irrigation between 3 days and 5days on all the parameters presented, but 3days irrigation had slightly the highest number of marketable fruit and weight of marketable fruit $hectare^{-1}$ while, 5days of irrigation had the maximum number of non- marketable fruit and weight of non marketable fruit $hectare^{-1}$. This shows that more irrigation was required at fruiting. There was also no significant difference of potassium on all the parameters presented, but 0 kg K_20 ha^{-1} had the maximum number of fruit, while 40 kg k_20 ha^{-1} had minimum fruits. This shows that potassium did not affect fruiting. Interactions of potassium and irrigation had no significant effect on number of marketable fruit and weight of marketable fruits $hectare^{-1}$ but number of non marketable fruit and weight of non marketable fruits $hectare^{-1}$ were significantly affected.

CONCLUSION

The result showed that irrigation at 3days had significantly increased plant height, number of branches and number of leaves. Also on the yield parameters, 3days of irrigation significantly increased the yield of tomato. Application of potassium at 0 kg K_20 ha^{-1} had significantly increased growth and yield parameters in tomato. It was an established fact that the amount of potassium required for the production ripened fruits of tomato considerably exceeded those required for maximum yield (Matev, 1995).

RECOMMENDATION

From the experiment conducted, 3 days of irrigation was recommended for maximum growth and yield of tomato to farmers in Samaru, Zaria.

ABSTRACT

Oryzaephius meccator commonly known as merchant grain beetle is often found infecting stored dika nut (Irvingia gabonensis). This study was conducted to proffer safe, environmentally friendly, cheap and affordable solution to the infestation. The objective of the study was therefore to: Determine and compare the effect of orange peel (Citrus sinensis), lime peel (Citrus aurantifolia) powders and aluminium phosphide on the storage parameters. Experiment was set up at the Faculty of Agriculture central laboratory, University of Ilorin, Ilorin, Kwara state. It was laid out in a Completely Randomized Design, each treatment was replicated three times and botanicals were applied at the rate of 2.5g, 5.0g, 7.5g, making a total of 24 experimental units, each involving 50g of dika nut and 10 adults of Oryzaephius meccator introduced to it each. Data was collected on the following parameters; adult mortality, oviposition, larval emergence and weight loss. Statistical analysis using ANOVA at a 5% significance level revels significant differences between the plant product treatments and the chemical control all through the 6 weeks experiment. It is concluded that the botanicals at the rate of 7.5g is more effective on adult morality at 6 weeks after infestation (1.33) and (0.33), oviposition at 6WAI (3.33) and (2.33), and larva emergence at 6WAI (0.67) and (0.00). It is recommended that the botanicals at high rate should be used in the management of insect pest of stored dika nut, for a more healthy, friendly environment and enhance food security.

Key words: *Orange Peel, Powder, Lime Peel, Aluminium Phosphide, Stored Insect Pests, Irvingia Gabonensis*

INTRODUCTION

Dika nut is an extract of wild mango (*Irvingia* spp.) which is grown for its fruits and kernels popularly known as ugiri and ogbono respectively in Nigeria. The edible fruit (*Irvingia gabonensis*) is eaten fresh or used to make juice and the kernel when ground is used to make ogbono soup but the no-edible (*Irvingia* spp) is solely grown for the production of ogbono from its kernels. The powder of the kernel is also used as ingredient in other sauces like tomatoes and groundnut for a sticky effect and taste (Achinewhu, 2019). Extracts of ogbono seed can be used to reduce obesity, cholesterol and chances of developing degenerative diseases such as diabetes, cancer, high blood pressure, kidney failure, heart attack and stroke (Agbor, 2017). The kernel composed about 62.8% lipids, 19.7% carbohydrates, 8.9% protein, 5.3% dietary fibre and 3.2% ash (Akusu and Kiin-Kabari, 2013).

One major insect pests is the merchant grain beetle (*Oryzaephilus mercator* Fauval), which lays its eggs between the testa and cotyledons of the seed or in cracks in the cotyledons, so that when the eggs hatch the larvae can feed on the cotyledons (Ejiofor and Okafor, 2017). Such insect infestation reduce the economic value of the kernel (Elah, 2020), thus the need for effective storage protection of the product. Usage of chemical insecticides offer effective protection to kernels.

MATERIALS AND METHODS

Study Location

The experiment was up at the faculty of agriculture central laboratory, University of Ilorin, Ilorin, Kwara State, Nigeria.

Source of Insects

The merchant grain bettles (*Oryzaephius meccator*) was obtained from existing culture at the insectanuim of the Nigeria stored products research institutes (NSPRI), Ilorin, Kwara State.

Preparation And Source Of Dika Nut

Dika nut was brought from Ipata market, Ilorin, Kwara State. After well picked, to separate the already dried ones, it was then stored in a covered plastic container and kept in the freezer for about 7 days. This was done to prevent the development of immature insects in the seeds. The seed were then spread after the eight-day set up for experiment.

Preparation of Plant Materials

Lime peel (*Citrus aurantifolia*) was brought from a local market in Ilorin, orange peel (*Citrus sinensis*) was sourced around Tanke area in Ilorin, Kwara State. The two plant materials were properly air-dried for two weeks, there after grounded with electric mill and sieved to obtain a fine powder.

Experimental Procedure

The experiment was laid out in a Completely Randomized Design (CRD). The treatment includes the powder of lime peel (*Citrus aurantifolia*) orange peel (*Citrus sinensis*) and the controls. Each treatment has three replicates.

For the experiment, 50% of dika nuts were weighed in to 24 plastic container (0.5mm) and the covered with Muslim cloth to allow aeration and also to prevent entry and exit of insects. First set of the experiment was treated with orange peel (*Citrus sinensis*) powder at different grams (2.5g, 5.0g, 7.5g). Each of the treatment at different levels of application has three replicates. Same procedure was repeated for the lime peel (*Citrus aurantifolia*) powder. The chemical which is the positive control was also replicated thrice but at just a single level of application. Also the untreated (negative control) was replicated thrice accordingly. Total number of 10 adults *Oryzaephius meccator* were introduced to each replicated. Keen observation was done, the treatments were added after a week of introducing the insect to the seeds. The effect of the treatments on *Oryzaephius meccator* was studied, counted and recorded on a week interval for 6 weeks. The seed weight loss as a result of the insect pest was recorded at the last week of the experiment.

Data Analysis

Data collected on adult insect mortality, larva emergence oviposition with the aid of microscope and weight loss caused by *Oryzaephius meccator* were subjected to one-way analysis of variance and where the differences were significant, the multiple comparisons of the treatment were done by using Tukey Honestly Significant Difference Test at P-value set at 5% level of significance. The statistical analysis was carried out using R Software (version 4.3.1)

Phytochemical Procedures

Determination of Total Phenolic Content

The amount of total phenolics in powders was determined with the Folin- Ciocalteu reagent. Gallic acid was used as a standard and the total phenolics were expressed as mg/g gallic acid equivalents (GAE). For this purpose, the calibration curve of gallic acid was drawn (Figure II). 1ml of standard solution of concentration 0.01, 0.02, 0.03, 0.04 and 0.05 mg/ml of gallic acid were prepared in methanol. Concentration of 0.1 and 1mg/ml of plant extract were also prepared in methanol and 0.5ml of each sample were introduced into test tubes and mixed with 2.5ml of a 10 fold dilute Folin- Ciocalteu reagent and 2ml of 7.5% sodium carbonate. The tubes were covered with parafilm and allowed to stand for 30 minutes at room temperature before and the absorbance was read at 760 nm spectrometrically

Determination of the Total Flavonoid

Aluminum chloride method was used for flavonoid determination. In this method Quercetin was used as standard and flavonoid contents were measured as quercetin equivalent. For this purpose, the calibration curve of quercetin was drawn (Figure II). 1ml of standard or extract solution (20, 40, 60, 80,100 mg/l) was taken into 10ml volumetric flask, containing 4ml of distill water. 0.3ml of 5%$NaNO_2$ added to the flask. After 5min, 0.3ml 10%$AlCl_3$ was added to the mixture. At the 6th min add 2ml of 1M NaOH was added and volume made up to 10ml with distills water. The absorbance was noted at 510nm using UV-Visible spectrophotometer

Determination Total Alkaloid Content

The total alkaloid content of the samples was measured using 1,10 - phenanthroline method described by Singh et al. (2004). 100mg sample powder was extracted in 10ml 80% ethanol. This was centrifuged at 5000rpm for 10 min. Supernatant obtained was used for the further estimation total alkaloids. The reaction mixture contained 1ml plant extract, 1ml of 0.025M $FeCl_3$ in 0.5M HCl and 1ml of 0.05M of 1, 10-phenanthroline in ethanol. The mixture was incubated for 30 minutes in hot water bath with maintained temperature of 70 ± 2^{o} C. The absorbance of red colored complex was measured at 510nm against reagent blank. Alkaloid contents were calculated with the help of standard curve of quinine (0.1mg/ml, i.e. 10mg dissolved in 10ml ethanol and diluted to 100ml with distilled water). The values were expressed as mg/g of dry weight

RESULT

Phytochemical Analysis

Tables 1: Phytochemical compounds in the orange peel (*Citrus sinensis*) and lime peel (*Citrus aurantifolia*) powders respectively.

SAMPLES	PHENOL Mg/l	FLAVANOIDS Mg/l	ALKALOIDS Mg/l
ORANGE PEEL POWDER	0.15	9.60	12.45
LIME PEEL	0.21	9.88	12.34

Table 1 revealed the phytochemical composition of the two *Citrus* spp consider in the present study. It was observed that phenol, flavonoids and alkaloids were all present in the *Citrus* spp. the present analysis indicated that both *Citrus spp* had a very low as compared to other constituents while alkaloids had higher quantity specifically in *Citrus sinesis* but lower flavonoids and phenols. The provided data presents a comprehensive analysis of different treatments' effects on infestation control, spanning various parameters such as adult mortality, larva emergence, percentage weight loss, and oviposition.

Effect of the *Citrus* spp. peel on Adult Mortality and Oviposition of *Oryzaephius meccator*

The effect of *Citrus* spp. powder on the adult mortality as shown in table 3. It was observed that the efficacy of the powder depends on the concentration level. The higher the inclusion level the higher the rate of adult mortality. Further observation revealed is the early adult mortality due to the quick action of the active chemical compound present in *Citrus* although it depends on the higher inclusion rate thereby with inclusion rate of 7.5g there was a less mortality observed at 6 weeks after infestation (WAI) since most of the insect had been controlled earlier as compared to the aluminum phosphide which eliminated all the insect pest at 1WAI and was left with no insect to controlled at week 2. The reason for this might be attributed to the presence of Limonene compound present in the peel of both *Citrus* spp. but at different concentrations.

Table 2: Effect of the Citrus *spp.* peel on Adult Mortality of *Oryzaephius meccator*

TREATMENT	Conc (g)	WEEKS AFTER INFESTATION (WAI) 1	2	3	4	5	6

The oviposition of the insect pest was observed with application of lime and orange peel powder at different inclusion rate which was presented in Table 3. There was significant difference observed with the inclusion of the powder of the two *Citrus* spp. when compared with control with no treatments.

Effect of the *Citrus* spp. Peel on Larva Infestation of *Oryzaephius meccator*

The larvae infestation effect was observed with different inclusion rate of *Citrus* spp. and presented in Table 4. The result revealed that there was a significant difference observed for the all inclusion rate, synthetic insecticide and the control considering the larvae infestation in the dika nut. It was observed that dika nut treated with aluminum phosphides had no larvae infestation. It was observed that the inclusion rate affected the larvae infestation. The higher the inclusion rate the lower the larvae infestation. It was further observed that at 6 WAI there was no significant difference observed between the application of Lime peel powder at 7.5g and the aluminum phosphides, this might be attributed to the chemical compound limonene which has been reported to have higher toxicity (Khanikor et al., 2021). It has been reported that the chemical composition of C. *aurantifolia* peel is 77.5% limonene and palatinol-1C which was responsible for the insecticidal activities while *Citrus sinensis* peel has basically about 90% limonene and other little quantity of 32 compounds. *Citrus sinensis* was reported effective against the fourth instar larvae and adults of some insect pest (Salem et al., 2013). The peel essential oils of *Citrus aurantifolia* has been reported as insecticidal, repellent, and larvicidal against *Aedes aegypti*. In a previous study, it was observed that the ovicidal, larvicidal and adulticidal effects of leaf and peel essential oil of *Citrus aurantifolia* against *Aedes aegypti* (Sarma et al., 2019).

Table 4: Effect of the Citrus *spp.* Peel on Larva Infestation of *Oryzaephius meccator*

TREATMENT	Conc (g)	WEEKS AFTER INFESTATION (WAI)

Effect of *Citrus* spp. on the Percentage Weight Loss of Dika Nut

The effect of *Citrus* spp. on the percentage weight loss of Dika nut was presented in Table 5. The effectiveness of *Citrus* spp. on the percentage weight loss of dika nut was as relevance with respect to the inclusion rate. It was observed that the percentage weight loss reduces with increasing inclusion rate for both *Citrus* spp. considered. The inclusion rate of 2.5g for both *Citrus* spp. showed a greater percentage loss which might be attributed to the minimal bioactive in *Citrus* to repel the insect pest considered while the higher the rate the lower the insect pest feed on the nut which implies that both *Citrus* spp. contain a repellant and antifeedant characteristics but effective at higher dosage. Although at the highest dosage considered, the percentage weight loss is still significantly different to the synthetic insecticide used. Aluminum phosphide reduced the percentage weight to negligible percentage but its residual effect might be questioned which is unsafe for human consumption.

Table 5: Effect of *Citrus spp.* on the Percentage Weight Loss of Dika Nut

Treatment	**Conc. (g)**	**Percentage weight Loss (%)**
Aluminum phosphide		0.94
Lime peel powder	2.5	13.49
Lime peel powder	5.0	9.19
Lime peel powder	7.5	4.61
Orange peel powder	2.5	14.33
Orange peel powder	5.0	10.45
Orange peel powder	7.5	6.05
Control		40.93

CONCLUSION

With the increasing awareness of consumers for ecofriendly products and at the same time increasing resistance of insect pests against insecticides, the demand for novel, safe and effective products is increasing. As discussed above, the existing literature revealed presence of a good number of terpene compounds in different *Citrus* species which are present in different ratios although in most cases limonene is the predominant constituent. Both the crude oil as well as individual compounds possess good insecticidal and repellent properties against diverse insect pests, both indoor and outdoor. The present study also showed promising potential against *Oryzaephius meccator* while using two *Citrus* peel powder with higher efficacy of *Citrus aurantifolia* and *Citrus* sinesis peel powders. The use of *Citrus* can be considered as an ecofriendly means of controlling O. *meccator* as against the aluminum phosphide

RECOMMENDATION

It is recommended that the further trials on citrus parts should be used in the management of insect pest of stored dika nut, for a more healthy, friendly environment and enhance food security.

ABSTRACT

This experiment was conducted at the Department of Crop Science Teaching and Research Farm, University of Nigeria, Nsukka (Nigeria) to evaluated the seedling emergence, growth performance, and fruit yield of a tomato variety (Cobra F1) grown under six (6) environments comprising varying polyethylene colour shades (including red, yellow, transparent, blue, and green) and the control treatment (where the tomato seedlings were grown in the open). Each of the growth environments was lined with four (4) plastic baskets where twenty (20) tomato seeds were planted out. The four baskets represented the treatment replications in completely randomized design (CRD) format. The growth medium was a mixture of topsoil, poultry manure and sawdust formulated in volume ratios of 3:2:1, respectively. Data were recorded on seedling emergence parameters (days to 1st, 50% and 100% emergence, total emerged seedlings), seedling height, number of leaves, stem girth, number of fruits per plant, days to 1st, 50% and 100% flowering/fruiting during the growth stages. The fresh fruit weight and fruit circumference were also studied. The early growth records showed that plants grown under polyethylene shades were significantly ($p < 0.05$) taller and produced higher number of leaves than the control plants grown in the open. Plants under the red shade showed superior performance (in terms of emergence records, seedling height and number of leaves per seedling) compared to other environments. Growth parameters studied at 10 weeks after planting (WAP) were significantly ($p \leq 0.05$) influenced by growth environment. Green and the yellow shade had the tallest plants (127.8 cm and 126.2 cm, respectively), whereas the non-shaded control plants were the shortest (76.0 cm). Plants under the transparent shade had the greatest number (22) of leaves, while the control plants had the least (9 leaves). Base and stem girth were thinnest under the red and yellow shades, while plants under the transparent shade had the largest girth size. Flowering and fruiting were earliest in the transparent and green shades, but were delayed under the red and control treatments. The transparent, followed by the green shade, recorded the highest number of fruits and total fruit yield per plant. The control (non-shaded) plants and those grown under the blue shade were the poorest in most of the fruit yield parameters. The use of transparent shade is therefore recommended for tomato production under Nsukka condition as it supported superior seedling growth and the highest fruit yield.

Keywords: *Tomato, polyethylene colour shade, fruit yield, Nsukka – Nigeria.*

INTRODUCTION

Tomato (*Solanum lycopersicum* L.) is an annual herbaceous crop that belongs to the Solanaceae family. It is one of the most widely cultivated vegetables in the world (Opena and Kyomo, 1990; Pierce 1987). Because tomato is a relatively short-duration crop and gives a high yield, it is economically attractive with widespread cultivation, and the area under cultivation is increasing (Naika *et al*., 2005). Tomato plays a vital role in human nutrition, serving as a rich source of vitamins and minerals, including vitamin C, potassium, and folate (Bjarnadottir, 2015). Among foods typically consumed by humans, tomatoes are particularly rich source of carotenoids. The visible red colour of the fruits is due to the quantities of carotenoids, such as lycopene and β-carotene, and chlorophylls inherent in them (Shi and Le Maguer, 2000). Red and orange colours result from the accumulation of lycopene and β-carotene, respectively. Green fruits contain chlorophylls, which usually degrade with ripening.

Tomato plants typically grow to a height of about 1 to 3 meters (Balajet *et al.*, 2017). They produce sprawling, fragile vines that usually require support. Tomatoes are cultivated across northern and southern parts of Nigeria, but the production concentrates more in the northern states like Sokoto, Kebbi, Plateau, Kano, Bauchi, Jigawa, Zamfara, etc., with longer durations of sunlight, lower humidity and clearer atmosphere. The most important constraint to tomato production in southern Nigeria is high air humidity and cloud cover, which characterize the climate of southern Nigeria.

There is an increasing interest in the use of controlled environment for growing horticultural crops. Some large commercial greenhouse farmers produce tomatoes, which give consumers access to the fruits at lean periods of the year when field-grown tomatoes are limited. Growing tomatoes in greenhouses or other controlled environments modifies the growth environment, and has great potential to influence the partitioning of crop growth resources, and sustainably enhancing yield. According to Read (2007), coloured films or plastics, also termed ‘high tunnel’ or ‘hoop house’, can have positive effects on the colour, size, and yield of tomato fruits. There have been several studies aimed at increasing tomato productivity in Nigeria both for small scale and commercial purposes. However, not much has been researched on the use of coloured shades to enhance tomato productivity in the southeastern Nigeria. Coloured polyethylene shades affect the spectrum of light that reaches the plants grown under the shades. Baiyeri (2006) reported that plants’ response to light would vary depending on the intensity and quality of the light they receive. Hence, the objectives of this study were to evaluate the seedling emergence, growth performance, growth phenology and fruit yield of tomato (*Solanum lycopersicum L.*) fruits grown under varying polyethylene colour shades in southeastern Nigeria.

MATERIALS AND METHODS

Study location

The experiment was conducted at the Department of Crop Science, University of Nigeria, Nsukka Research Farm, from February to October 2022. The climate of Nsukka (latitude 06°51'E, longitude 07°29'N, 475m a.s.l.) is characterized by lowland humid condition with bimodal annual rainfall of 1155mm to 1955m (with peaks in July and September, and a short break in mid-August), mean annual temperatures of 29°C to 31°C and a relative humidity ranging from 50 to 90% (Uguru *et al*., 2011) in a derived savannah ecology. The soil of the experimental site is ultisol (Asiegbu, 1989).

Experimental Design

The experiment evaluated the seedling emergence, growth performance, fruit yield and fruit nutritional quality of a determinate tomato variety (Cobra F1) grown under six (6) environments. The growth environments consisted of varying polyethylene colour shades (including red, yellow, transparent, blue, and green) and the control treatment (where the tomato seedlings were grown in the open). Each of the growth environments was lined with four (4) plastic baskets where twenty (20) tomato seeds were planted out. The four baskets represented the treatment replications in completely randomized design (CRD).

Treatment application

Topsoil, poultry manure and sawdust mixed in volume ratios of 3:2:1 (v/v/v, respectively) was used as the growth medium. The substrates were thoroughly mixed, moistened and covered for composting. The growth medium was turned and moistened fortnightly (to maintain the moisture level) until the composting was completed after four months. Four litre plastic baskets were filled with the formulated growth medium and laid, four each, inside the shades and planted with twenty (20) tomato seeds each.

Data Collection

Nursery Stage: Data were collected on days to 1st seedling emergence, days to 50% seedling emergence, days to 100% seedling emergence, and total emerged seedlings per basket. At 2 to 4 weeks after planting (WAP), data were collected from four sample plants per basket on plant height (cm) and number of leaves per seedling.

Seedling growth stage: At the completion of seedling emergence at 4 WAP, the seedlings were thinned down to one per basket and growth data were collected on plant height (cm), number of leaves per seedling, stem girth (cm) at the mid-stem height, and seedling base girth (cm) which was measured at the soil level.

At 8 to 10 WAP, data were collected on plant base girth (cm), plant height (cm), number of leaves per plant, stem girth (cm) at the mid-stem height, number of flower trusses per plant, number of branches per seedling, and total number of leaflets per seedling. At flowering, data were collected on days to first flowering, days to 50% flowering, days to 100% flowering, days to 1^{st} fruiting, days to 50% fruiting, and days to 100% fruiting.

At harvest, data were recorded on days to 1^{st} harvest, number of harvested fruits per plant, total fruit weight (kg) per plant, days to last harvest. Fruit circumference (cm) was measured from 15 composite fruits per treatment.

Statistical Analysis

All the data obtained were subjected to analysis of variance (ANOVA) according to the procedures outlined for completely randomized design (CRD) experiments using GenStat 10.4 analytical software. Detection of differences between treatment means was done using Fisher's least significant difference (F-LSD) at 5% probability level.

RESULTS

Table 1 shows the seedling emergence parameters of tomato (*Solanum lycopersicum*) as influenced by nursery colour shades. The colour shades did not have a significant impact on most of the emergence parameters studied. However, the red shade had the shortest days to 1st and 50% seedling emergence (7.0 and 10.8 days, respectively) and recorded the highest emergence percentage (88.8%) compared to the rest of the growth environments. The control (non-shaded) environment had the longest days to 1st and 50% seedling emergence (9.5 and 13.5 days, respectively). Percentage seedling emergence was the poorest (70.0%) under the blue shade, followed closely by the control environment (75.0%).

At 2 and 4 weeks after planting (Table 2), all the plants grown under polyethylene shades (irrespective of the colour) were significantly ($p < 0.05$) taller than the control plants grown in the open. The plants under the colour shades also produced significantly ($p < 0.05$) higher number of leaves than the control plants grown in the open. At 2 weeks after planting (WAP), the blue shade had the tallest plant height (39.0 cm), and with the red shade produced seedlings with the greatest number of leaves (16), compared to the control plants with 7 leaves and height of 12.0 cm. At 4 WAP, the seedling heights across the colour shades were statistically similar, but the red and the transparent shades had seedlings with the greatest number of leaves (27 and 26, respectively), compared to the control plants which had 14 leaves per seedling.

At 8 WAP (Data not shown), most of the seedling growth parameters were significantly ($p \leq 0.05$) influenced by the varying colour shades. Seedling heights were similar across the colour shades, but plants under the polyethylene colour shades were statistically ($p < 0.05$) taller than the non-shaded control seedlings. The yellow and green shades had the tallest seedling height (99.8 cm and 95.2 cm, respectively), while the control treatment had the shortest (51.2 cm) seedlings. Number of leaves and leaflets per seedling were statistically ($p > 0.05$) similar across the treatments, but the control and the red shade had the least values across the treatments.

Seedling base girth, stem girth and number of flower trusses per plant were significantly influenced by the varying colour shades. Base girth and stem girth were the poorest under the red shade, but similar across the other treatments. Seedlings under the transparent polyethylene shade produced the highest number (5.0) of flower trusses, followed by the green (3.5) and blue shade (3.0), respectively. Plants under the red shade had no (zero) flower at 8 WAP, while the control plants and those under the yellow shade had 1.8 and 2.5 trusses, respectively. It is worthy to note that the red shade had already faded its colour at 8 WAP, necessitating a colour spray which produced an opaque effect restricting some light transmission within the chamber, thereby affecting the overall seeding performance.

All the growth parameters studied at 10 WAP were significantly ($p \leq 0.05$) influenced by the colour shade treatment (Table 3). Green and the yellow shade had the tallest plants (127.8 cm and 126.2 cm, respectively), followed by the blue shade (116.5 cm), whereas the non-shaded control plants were the shortest (76.0 cm).

Plants under the transparent shade had the greatest number (22) of leaves, although not significantly different from the 19, 17 and 16 leaves recorded under the yellow, green, and blue shades, respectively. The control plants had the least number (9) of leaves. The number of leaflets was highest (127) under the yellow shade, followed by the green (102) and the blue shade (92), and least with the red (57) and the control plants (66 leaflets). Plant base girth and stem girth were poorest under the red and yellow shades, while plants under the transparent shade had the largest girth size. Number of flower trusses at 10 WAP (Table 3) was highest (10 trusses each) under the transparent and green shades, followed closely by the yellow (with 8 flower trusses), while plants under the red shade had only one (1) flower truss at 10 WAP.

Delayed flowering was observed in plants grown under the red shade as evident in the number of days to 1st and 50% flowering (Figure 1). Plants grown under the red and yellow shades had the longest days to 100% flowering, followed closely by the unshaded control plants. Plants grown under the transparent (colourless) shade had the earliest flowering. Variability in days to 1st and 50% fruiting across the colour shades was not glaring; however plants under the red shade did not eventually fruit owing to the poor light transmission within the shade after a clour spray was applied to restore the faded polyethylene colour.

The varying colour shades had no significant influence on days to 1st fruit harvest, days to last harvest, and the mean fruit circumference per plant (Table 4). However, number of fruits harvested per plant, total fruit yield per plant and the mean fruit weight were significantly ($p < 0.05$) influenced by the varying polyethylene colour shades. The transparent shade, followed by the green shade, recorded the highest number of fruits and total fruit yield per plant, although the green shade had the least mean fruit weight. The control (non-shaded) plants and plants grown under the blue shade were the poorest in most of the fruit yield parameters.

DISCUSSION

Plants are highly adaptable organisms, but their growth and productivity are greatly influenced by the environment in which they are situated (Mendes *et al.*, 2013). According to Khandaker (2010), polyethylene colours used as shades have distinct optical characteristics and thus reflect different radiation patterns into the canopy of crops, thereby affecting plant growth and development. The discernible differences in the seedling emergence, growth performance, and fruit yield observed in this study are attributable to the variations in light penetration allowed into the growth environment. In the overall, the tomato plants grown under the polyethylene colour shades outperformed the control plants grown in the open.

Seedling emergence and growth performance of tomatoes

It was observed that polyethylene colour shades did not have significant influence on the seedling emergence, however, red coloured shade caused early emergence and vigorous seedling growth when compared to other colours. Although the control and transparent shade did not support rapid height increments in the tomato plants, other colour shades (probably due to their reduced light penetration) caused an increase in height of the tomato plants grown under them, particularly at the early juvenile stages. This is in consonance with the work of Stamps (2009) on shade netting, where darker shades reduced photosynthetically active radiation (PAR) the most, which caused elongated internode, increased number of leaves, shoot length, and leaf width compared to the no-net control. Blue light can stimulate stem elongation by promoting cell elongation in the stem's internodes (Briggs, 2002), which results in increased plant height. However, this increase in height did not translate to enhanced productivity of the plants. The blue shades caused an increase in the number of leaves per seedling in the first few weeks of the plants growth. This agrees with the work of Ito *et al*. (2006) on Phalaenopsis cultivars and hybrids, where blue netting showed a fairly consistent pattern of enhanced foliage biomass production despite reduced transmission of PAR compared with black and red nets.

The positive influence of the transparent shade was not very glaring during the early growth of the tomato plants, however the transparent shade had a great influence on the number of leaves per plant during the productive stage of the plants. The distinctive characteristics of transparent polythene and its impact on light transmission and plant growth may be responsible for the significant differences in stem girth, base girth, and the number of flower trusses observed under transparent shades. Transparent polyethylene allows a wide spectrum of light, including all visible wavelengths, to pass through. This provides the tomato plants with the full spectrum of light needed for photosynthesis and growth (Smith, 1995). This result agrees with the work of Shahak *et al.* (2004) where red/white shade net treatment that reduced PAR by 18% increased fruit set of apple compared with the no-net control. Transparent polyethylene ensures that the plants receive optimal light for photosynthesis (Hogewoning et al., 2010), and adequate photosynthesis supports greater carbohydrate production, which could lead to increased leaf production and expansion. Another important point to note is the influence of the transparent shade on the stem girth. Tomato is very susceptible to lodging due to its weak fragile stem, so the transparent shade helped to increase the stem girth and reduce lodging effect.

Influence of polyethylene colour shades on the tomato yield

Adequate light is crucial for the initiation and development of flower trusses in tomato plants. According to Hogewoning *et al.* (2010), consistent light exposure throughout the growth period supports continuous photosynthesis and carbohydrate production. This condition allows for optimal light penetration into the plant canopy, leading to larger fruit size. Transparent polyethylene shade provides optimal light conditions for photosynthesis and plant growth, leading to increased leaf production, thicker stems and bases, and more flower trusses and fruiting in tomato plants compared to other coloured shades.

CONCLUSION

(1) In the overall, it was found that polyethylene shades provided the tomato plants with optimal growth conditions than the non-shaded control treatment.
(2) Among the studied polyethylene colour shades, the transparent shade had much positive effect on the tomato productivity than other shade colours.
(3) It is evident from the study that shaded tomato plants outperformed the non-shaded control plants in terms of seedling growth, fruit yield and overall fruit quality.
(4) Tomato production under controlled environment, particularly with transparent polyethylene cover is recommended for the emerging tomato industry in Nsukka southeastern Nigeria.

ABSTRACT

Soybean is reputed to be better at fixing atmospheric nitrogen than cowpea and therefore has a higher potential to improve soil fertility. However, soil acidity which is characteristic of intensely farmed soil is a constraint to soybean production in Nigeria. on average yield of 0.93 t ha^{-1} are reported from farmers' fields as against a potential of more than 3.5 t ha-1 for improved varieties under optimal growth conditions. This study evaluated the effect of four rates of lime on growth and yield of soybean on acidic soil. Field experiments were carried out at Value Seed Production fields situated in Northern Guinea savanna agro-ecological zone in Nigeria between July and November, 2022 to assess the effect of four rate of liming on growth and yield of soybean in acidic soil. The experimental designs was 4 x 2 factorial experiments comprising of four rates (L0 =no application, L1=400 kg/ha, L2 = 800kg/ha, L3 = 1200 kg/ha) and two soybean varieties (V1 = TGx 1951-3F and V2 = TGx 1904-6F). The trials were arranged in a Randomized Completely Block Design, replicated thrice. Data were collected on growth and yield parameters, and were subjected to analysis of variance. Means were separated using Duncan's Multiple Range Test and significance level was tested at 5% level of probability ($p \leq 0.05$). Pre cropping soil analysis indicated the soil was strongly acidic (4.89) and the post cropping soil analysis shows that the liming rate of 800kg/ha and 1200kg/ha had a significant effect on the acidity level of the soil to moderately acidic (6.33 and 6.74) The liming rate of 800kg/ha significantly improved the growth and yield parameters of both varieties compared to the no application of lime. Higher seed weight per plant was observed with the application of 800kg/ha (TGx 1904-6F = 32g and V1= TGx 1951-3F = 29.30g). In conclusion, appropriate rate liming rate was the most important factor for changes in pH, therefore ameliorating the soil to improve the growth and yield of the crop for subsequent cropping.

INTRODUCTION

Soil acidification which is decrease in soil pH limit crop yields and can diminish farmers' incomes. Soil pH can easily be increased by application of lime, in practice application must be economically viable with yield benefits offering an acceptable return on investment. Liming is a long-term investment with carry-over benefits. Adopting long-term economic strategies in crop production can be challenging for farmers who lack investment capital and who may have short-term decision time frames, which is peculiar with most smallholder farmers in sub-Saharan Africa (Mahamood *et al*., 2009). In addition, application of lime causes substantial greenhouse gas (GHG) emissions (especially CO2). It is currently unclear how liming affects on a per hectare basis affect GHG emissions per tonne of crop produced.

Soybean (*Glycine max* (L.) Merill) is a legume plant that belongs to the botanical family *Leguminosae*. It is an economically significant leguminous crop globally and it is among the main crops that are grown in Nigeria. According to Dugje *et al*. (2009), soybean has higher protein content than any of the common vegetable or legume food crops in Africa. It contains 20-25% edible oil and 42-45% protein contents (Alam *et al*., 2009). Soybean has potential to address protein and oil deficiencies (Mahamood *et al*., 2009). It produces significantly more protein per hectare than any other leguminous crop and is good source of unsaturated fatty acids, minerals (Ca and P) and vitamins A, B, C and D (Alam *et al*., 2009).

Nigeria is the largest producer and consumer of soybean in Sub-Saharan Africa (Dugje *et al*., 2009). Soybean cultivation in Nigeria has expanded as a result of its economic and nutritive uses. Soybean meal and full fat soya are a major source of protein and calories in the livestock industry. The rapid growth in the poultry sector between 2004 and 2009 has also increased demand for soybean meal in Nigeria (Dugje *et al*., 2009). It is expected that soybean production will increase as more farmers become aware of the potential of the crop, not only for cash/food but also for soil fertility improvement and *Striga* control (Dugje *et al*., 2009). The crop can be successfully grown in many states in Nigeria with little investment in agricultural inputs. Production is mainly done by small farm holders on farms of less than five hectares (ACET, 2013). Average soybean yield of 1t/ha have been reported in farmers field (FAO, 2014)), which is much lower than 3t/ha achieved on research stations in Nigeria (Tefera, 2011).
Soybean production is mainly constrained by diseases such as soybean rust (Twizeyimana *et al*., 2008) and moisture stress (Tefera, 2011) and soil nutrient deficiency (Kamara *et al.,* 2007; Kolawole, 2012). Other constraints are limited access to good input such as fertilizer, inoculants, herbicides and insecticides (ACET,2013).
According to von Uexkull and Mutert (1995), acid soils occupy about 30% of the world's ice-free land area. Plant growth-limiting factors in acid soils include N, P, Ca, Mg, Mo, and Zn deficiencies and/or Al, Mn, Fe, and H toxicities. Mengel and Kirkby (2001) reported that the efficiency of added N, P, and K fertilizers was very low in acid soils. Moniz *et al*. (1997) recommend a combination of soil management practices as way to improve crop production in acid soils: liming in combination with corrective levels of P and the use of crop cultivars developed for low pH conditions. Naturally occurring minerals that are commonly used to raise soil pH are limestone (CaCO3) and dolomite ($CaMg(CO_3)$). In addition, waste products from manufacturing processes using limestone or similar raw materials can be used for neutralizing soil acidity. Liming and increased P fertilization are common recommendations for improvement of pseudogley soils in Croatia (Kisic *et al*. 2002; Petosic *et al*. 2003; Komljenovic *et al*. 2006). To successfully grow field crops on acid soils, liming, alone or in combination with mineral and organic fertilization, is recommended worldwide (Komljenovic *et al*. 2006).
The aim of this research is to know the effect of different rate of calcium carbonate on growth and yield of soybean cultivated on acidic soil

MATERIALS AND METHODS

Experimental Site

Field experiments were carried out at Value Seed Production field in the Northern Guinea Savanna agro-ecological zone of Nigeria (N11^0 14.559" E007^0 45.659") between July and November, 2022.

Pre and post-cropping soil sampling and analysis

The field was laid out in blocks of different areas and sampling was done per block. A minimum of 10 spots were sampled per composite/bulk sample which was mixed together and quartered accordingly. A minimum of one sample were taken per block depending on the variation of the field. Sampling was done with a soil auger at 0-15cm soil depth and the samples were bulked into a composite sample. The samples were air dried, crushed and sieved through 2 mm and 0.5 mm meshes for the determination of particle size, soil pH, electrical conductivity, organic Carbon, total Nitrogen, Phosphorus, Potassium, magnesium, iron, copper, zinc, manganese and boron. This were determined using harvesto digital soil testing machine (model WST – 314P). A post-harvest composite soil sampling was obtained at a depth 0 – 15cm on each representative plot six weeks after planting.

Treatments and experimental design

The Experimental site was cleared and prepared manually using simple farm tools. The experimental fields was divided into four blocks which comprised four levels of liming material (calcium carbonate). These were L0 (no application), L1 (400 kg/ha) L2 (800kg/ha) and L3 (1200 kg/ha). Two medium - maturing varieties of soybean were planted which are V1 (**TGx1951-3F**) and V2 (**TGx 1904-6F**) were the test genotypes. The experimental layout was a factorial experiment (4 x 2) laid out in a randomized complete block design (RCBD), replicated three times. Application of calcium carbonate was done on each plot base on the concentration allocated to each plot and the second harrowing was done for the lime to be thoroughly-worked into the soil. Broadcasting of diammonium phosphate (DAP) fertilizer was done at the rate of 120kg /ha. A bed size of 4 m x 2 m was made and the crop spacing was 50 cm x 50cm and seeds were sown at two stand per hole. Weeding was done at six weeks after planting (6WAP). Four plants from each subplot were randomly selected for the determination of the number of root nodules/plant, plant height and number of leaves /plant. Pod harvesting was done when the leaves had senesced and the pod turned brown and data were recorded on the number of pods per plants, number of seeds /plant and seed weight /plant. All data collected were subjected to analysis of variance (ANOVA) and means were separated using Duncan Multiple Range Test at 5% probability level.

RESULTS AND DISCUSSION

As indicated on Table 1 and 2, the pre-cropping and post-cropping soil samples were texturally sandy-loam. These results agree with Odunze (2003) who opined that the soils in the Northern Guinea Savannah are sandy to sandy-loam in texture. They have low available soil moisture retention capacity and encourage leaching of nutrients away from the rooting depth of most crops. The soils therefore become degraded due to effects of soil erosion, deforestation, overgrazing, nutrient mining and poor soil management strategies applied by farmers.

As observed in Table 3 application of Calcium carbonate at the rate of 800kg/ha significantly increased the growth parameters with crop height (101.3cm) and number of leaves (108), this was observed from the variety TGx 1951-3F. From Table 4 the application of 800kg/ha of calcium carbonate also increased the numbers of seeds per plant (367and 316) and this was observed on the two varieties cultivated. It also increases the seed weight per plant (32g and 39g). With all the aforementioned observation the application of calcium carbonate enhances the growth and yield of soybean. This was in line with (Chan and Heenan 1998; Bolan *et al*. 2003; Jaskulska *et al*. 2014), Which state that liming increases crop production primarily through direct effects on improving soil physical, chemical, and biological characteristics, which lead to increased availability and mobility of many plants' essential nutrients.

The increased nodulation observed in this study may be attributed to effect of lime application which lead to favorable condition for microbial activity by regulating the pH values. This was observed with crop with the application rate of 800kg/ha. France and Day (1980) had reported that liming of acidic soil increase nodulation and nitrogen fixation of *Phaseous vulgaris* (L) in acid which are in agreement with the results obtained in the study. Generally, the application of 400kg/ha of Calcium carbonate suggest that the soil was poorly buffered at the rate of 400kg/ha. Plant height, number of leaves and stem girth was affected significantly by 800kg/ha of lime application, while the other lime rates and its interaction did not significantly affect plant height. Liming at the rate of 800kg/ha and 1200kg/ha also increased number of pods irrespective of the varieties when compared to other rate of application. This is in line with Taufiq *et al.* (2011) who reported that application of appropriate liming material can increase plant height, number of pods per plant, and yield.

CONCLUSION

As indicated in this study, liming can lead to ample changes in soil pH, which in turn improve the soil productivity. This can lead to significant improvement of soybean yields in the Northern Guinea Savanna agro-ecology.

Table 1: Pre-cropping soil physical and chemical properties

Soil Characteristics	Values
pH (H_2O)	4.89
Organic Carbon (%)	0.24
Total N (kg ha^{-1})	87.2
Available P (kg ha^{-1})	5.18
Available K (kg ha^{-1})	197.2

ABSTRACT
The effects of N and K fertilizers rates on the growth, yield and nutritional qualities of fluted pumkin was investigated during the 2022 cropping season at the Teaching and Research farm, Ladoke Akintola university of Technology Ogbomoso. The 3x5 factorial experiments were laid out in Randomized Complete Block Design with three replications. Result shows that applied N and K fertilizer rates significantly increase the number of leaves, vine length, fresh shoot and nutritional quality of Telfairia with the optimum values obtained from the sole application of 60Kg N and 60Kg K_2O/ha. Although, the combined application of 60KgN/ha +15Kg K_2O/ha gave highest fresh shoot yield, but there were no significant difference between this values and that at 30KgN +15KgK_2O/ha. In conclusion, application of 60KgN/ha and 15KgK_2O/ha gave the highest marketable yield of Telfairia in Ogbomoso.

INTRODUCTION

Telfairia occidentalis (Hook.F.) known as fluted pumpkin or *Telfairia* is a member of the family cucurbitaceae (Schippers, 2002). The crop is commonly called Ugu by the Ibos of South Eastern Nigeria. It is often planted solely from seeds often close to fences and walls to provide support for the shoots (Lathan, 2002). *Telfairia* occidentalis leaves are palatable and nutritious (Olomola *et. al*., 2006). The leaves of fluted pumpkin are used in soups and porridges as the vegetative parts of the crop make an excellent vegetable rich in vitamins and has 37.3% protein content on a dry weight basis (Schippers, 2002). The leaves are medicinal and used for the treatment of anemia and diabetes (Akanbi *et. al*., 2007). The tender vine and foliage are eaten as a pot herb, while the seed is consumed as a nut (Akoroda, 1990). The seed contains 20% protein, 45% fat, 23% carbohydrate, 2.2% fibres, and 1.8% total ash. The oil in the seeds is non-drying and contains lactating properties which are in high demand by nursing mothers (Akanbi *et al.,* 2007). The oleic and linoleic acids constitute over 63% of the fatty acids and that makes the oil useful in soup making and cooking, suitable for use in the manufacturing of pomade, margarine and as well as a carrier for certain drugs (Akanbi *et al.,* 2007).

The leaf has high nutritional, medicinal, and industrial values being rich in protein (29%), fat (18%), and minerals and vitamins (20%) (Tindall 1986). The oil in the seeds is non-drying and is useful in soap making and cooking (Fashina *et. al*., 2002). Also, Asiegbu (1987) reported that the protein and oil content of the seed is 30.1% and 47% respectively. The composition of the seed per 100g edible portion is water 6.0g; energy 2280kj (543k cal); protein 20.5g; fat 45.0g; carbohydrate 23.5g; fiber 2.2g; calcium (Ca) 84mg and Phosphorus (P) 572mg; (Leung *et. al*., 1968). The seeds are high in essential amino acids (except lysine) and can be compared to soya bean meal with 95% biological value. The fruit pulp has a protein content of about 1.0%. The main constituents of the seed oil are oleic acid (37%), steric and palmitic acid (both 21%); and linoleic acid (15%) (FAO,1988). In Nigeria, there is a widespread problem of soil degradation due to continuous cultivation of the soil (Schippers, 2002).

One of the problems of crop production in the tropics is that tropical soils have low fertility status (Agbede 2010). The soils are highly weathered and leached, low in organic matter and available nutrients, thus leading to low productivity within few years of cultivation (Soremi *et. al*., 2017). Applying inorganic fertilizer is one of the widely accepted ways of increasing soil nutrients both in the temperate and tropical

zones of the world. It has been reported that Nitrogen (N), Phosphorus (P), and Potassium (K) are the major essential elements required for physiological mechanisms for plant growth, with increasing pressure on soils of southwestern Nigeria, shifting cultivation is no longer sustainable and traditional bush fallow period for maintaining the productivity of the soil has become shorter and soils are no longer able to supply the number of nutrients required with the result, that yield level declines rapidly once cropping commences (Amhakhian *et. al*., 2010). Therefore, there is a need to augment soil fertility with external sources of nutrients. However, organic inputs alone will not meet the nutritional requirements of crops because they contain comparatively lower quantities of nutrients compared to inorganic fertilizers. Hence, the need to integrate the two forms to achieve better crop yields (Khan *et. al.,* 2008; Suge *et. al.,* 2011).
Although, many research activities have reported better performance of crops with fertilizer application; one of the methods through which plants would display their potential genetic capability is by supplying the plants with adequate amount and types of fertilizer at the right time (Aliyu, 2003; Olaniyi *et al*., 2010). Research efforts are therefore required to recommend combination of N and K fertilizer for sustainable production of *Telfairia* occidentalis in Ogbomosho

MATERIALS AND METHOD

The experiment was conducted at Teaching and Research Farm Ladoke Akintola University of Technology, Ogbomoso (8^0 10'N and 4^0 10'E), a location in the Guunea Savannah zone of South-western Nigeria. The treatment was laid out in a factorial experiment and fitted in a Randomized Complete Block Design (RBCD) with 3 replications. The experimental plot was divided into three blocks each containing 15 beds to give a total of 45 beds. The treatments involved three Nitrogen fertilizer rates (0, 30, 60kgN/ha) applied in form of Urea and Five Potassium fertilizer rate (0, 15, 30, 45, 60kgK/ha) applied in form of Muriate of Potash and their various combinations. Each bed size was 1.2m x 1.2m and 0.5m spacing within and 1m between beds to ease movement during cultural operations.
Planting was done in early April, with fluted pumpkin seeds procured from the Department of Crop Production and Soil Science, LAUTECH, Ogbomoso. Four seeds were sown at a spacing of 1m x 1m and later thinned down to two seedlings per stand at four weeks after sowing (WAS). The different fertilizer rates were applied to their respective plots according to the treatment combinations at 6 weeks. The fertilizer application was by band placement, watering was done every morning at 2 days interval during the drought periods to avoid wilting of the plant, staking, weeding and other crop management took place as at when due. Data were collected four weeks after planting and repeated at two weeks interval. Variable assessed include vine length, number of vines, number of leaves, height of the plant per plot and dry matter yield. Data collected were analyzed using Analysis of Variance (ANOVA) by the SASGLM procedure. The differences between treatment means were separated using the least significant difference at 5% level of probability.

RESULTS AND DISCUSSION

There were no significant differences ($p> 0.05$) among the number of leaves of fluted pumpkin with the fertilizer rates at 4, 6 and 10 WAS. At 4 WAS, the combined application rate 30 kg N/ha+60 kg N/ha produced the highest number of leaves (13.22) while 30 kg N/ha +30 kg N/ha recorded the least value of 8.44. At 12 WAS however, the highest number of leaves (79.33) was produced by combined rate 30 kg N/ha+ 60 kg N/ha while control recorded the least value of 44.89. The vine length increases as the plant aged (Table 2). Rate of applied fertilizer did not significantly ($p>0.05$) influenced the vine length throughout the experimental period. There were no significant differences ($p>0.05$) among the vine length throughout the period of the study. The combined application rate of 30 kg N/ha+45 kg K/ha produced the highest vine length while the lowest vine length was produced at 30kgN/ha fertilizer application. The fresh shoot yield as influenced by fertilizer rate and types are presented in Fig1. These were no significant difference ($p>0.05$) among the fresh shoot yield across the period of study. The combination of 60 kg N/ha+15 kg/ha produced the highest fresh shoot yield, closely followed by combined application of 60 kg N/ha+30 kg N/ha and the lowest fresh shoot yield was recorded from 30 kg N/ha fertilizer application.

The nutritional qualities of fluted pumkin are presented in table 3. The nutritional qualities of Fluted pumkin were significantly influenced by the fertilizers applied for the entire nutrient tested. The highest value was obtained from the combined application of 60 Kg Nha^{-1} + 60 Kg K_20 ha^{-1} except for Phosphorus that recorded highest value at 30kg K_20 while control recorded the least value for all the nutrients tested.

DISCUSSION

The increased in the vine length, number of leaves and shoot yield confirms the earlier reports of other researchers (Akanbi *et al.,* 2008; Shiyan and Binang, 2014; Usman, 2015), that nutrient availability is a major determinant of the crop photosynthesis capacity. The higher leaf area development indices and vine growth parameters observed with increased fertilizer application suggests that these crop parameters can produce their potential capacity when soil nutrients are made available. Cechin and Fumis (2004) also observed high leaf development and shoot dry matter production in sunflower with increased nutrient supply. The enhanced growth of pumpkin in this study is due to rich nutrient content of applied fertilizer. The availability of nitrogen, phosphorus and potassium is essential for photosynthesis activities and enhance dry matter accumulation (Zhang *et al.,* 2006; Matsi, 2012). The improved performance with nitrogen and potassium combination may also be attributed to increase in soil quality.

Olsen *et al.,* (1993) and Olaniyi (2006) observed similar effects for pepper and melon respectively. The distribution of protein, fat and fiber and other minerals in the plant part of the fluted pumpkin was highly influenced by the applied amendment. This showed direct relationships between soil nutrients content and plant uptake of the nutrient. The 1.9 to 2.3% protein content obtained in the study is closer to 2.9% protein recorded for pumpkin leaves per 100g edible portion by FAO (1998) and the observed difference may be attributed to the variations in the experimental environment. However, the application of combined nitrogen and potassium produced the maximum quantity of the nutritional components signifying that the two elements are essential; nitrogen is an important component of all organic compounds while potassium is important for cell activities. Hence the observed result from their combination in fertilizer mixes.

CONCLUSION AND RECOMMENDATION

The application of inorganic fertilizer in this study influenced the numbers of leaves, vine length and fresh shoot yield of *Telfairia* occidentalis. From the result, the application of 60kgN/ha+15kgKha gave higher fresh yield however, since there were no observed significant differences between 60kgN/ha+15kgK/ha and 30kgN/ha+15kgK/ha in fresh marketable yield, it would be more economical to cultivate the pumpkin plants using rate 30kgN/ha+15kgK/ha. This will allow for proper development of plant growth parameters for maximum fresh marketable yield at a reduced cost.

ABSTRACT
Okra (Abelmoschus esculentus) is grown in the tropics and sub-tropics. Infection by Sclerotium rolfsii can result to serious economic losses to farmers. The use of synthetic fungicides to control diseases in crops are inimical to our environment and human health. This study evaluate the bio-control potential of two Trichoderma isolates against Sclerotium rolfsii causing southern blight disease of okra using pot culture experiment in the screen house. The treatments considered in a completely randomized experimental design (CRD) were: i) T. harzianum; ii) T. viridae; iii) T. harzianum + T. viridae; iv) mancozeb; and v) pathogen inoculated only (control). Data was collected on growth parameters of okra and on the incidence and severity of the disease. Analysis of variance was conducted on the data using R software version 4.1.2 and means were separated using Tukey test at 5% level of significance. The results showed significant difference (p<0.05) in the growth parameters and disease incidence in which all the Trichoderma treatments performed better than the control. It could be concluded that the Trichoderma isolates have the ability to suppress the incidence of southern blight disease of okra.

INTRODUCTION

The production of vegetables has become very popular in many countries of the world due to its importance in the diet of the people. Their production has been recognized as the most affordable and accessible sources of micronutrient and a means of generating and increasing foreign exchange in Africa (AVRDC, 2004). Okra is the most important fruit vegetable crop and a source of carbohydrate, proteins and vitamin C in large quantities (Adeboye and Oputa, 1996). It ranks first before other vegetable crops in Nigeria (Babatunde *et al.,* 2007). It is also one of the most commonly grown vegetable crops in the tropics. Okra cultivation and production has been widely practiced because of its importance to the economy and can be found in almost every market in Africa. Christo and Onuh (2005) documented that okra is consumed throughout Nigeria. The leaves, buds and flowers are also edible. Okra seed could be dried. The dried seed is a nutritious material that can be used to prepare vegetable curds, or roasted and ground to be used as coffee additive or substitute (Farinde *et al.*, 2001).

India is the world's leading producer of okra, producing 3.5 million tonnes (70% of total global production) on approximately 0.35 million hectares of land while Nigeria ranked first in Africa with 1.53 million tonnes (80% of global production) of total generated from 0.15 million hectares of land (FAOSTAT, 2008). Productivity of the crop is low in West and Central Africa with average productivity of (2.5 t/ha) compared to East Africa (6.2 t/ha) and North Africa (8.8 t/ha). Worldwide, India is the largest producer followed by Nigeria and Sudan (Varmudy, 2011).

Okra crop suffers from a number of biotic and abiotic factors, including insect pests and diseases. Southern blight disease caused by *Sclerotium rolfsii* is a devastating soil-borne fungal disease that is reported to infect a wide range of crops in different parts of the world including Africa (Liamngee Katoor et al, 2015). The disease has been reported on common bean (*Phaseolus vulgaris*) in Uganda (Paparu et al. 2018), India (Mahadevakumar et al. 2015), and Italy (Garibaldi et al. 2013); maize (*Zea mays*) in Pakistan (Yasmin et al. 1984); soy bean (*Glycine max*) in Nigeria (Akem and Dashiell 1991); potato (*S. tuberosum*) in Italy (Garibaldi et al. 2006); okra (*Abelmoschus esculentus*) in Cote d ˆ 'Ivoire (Kone et al. ´ 2010); and sesame (*Sesamum indicum* L.) in Mexico (Hernandez- ´ Morales et al. 2018). Studies have been carried out in Nigeria that shows susceptibility of okra to *Sclerotium rolfsii* and infestation can cause serious economic losses to farmers (Ekundayo et al, 2018).

Soil treatments with chemicals are often less sufficient and there is the need to reduce their usage because of adverse effects on the environment. Biological control through the use of antagonistic microorganisms has become very relevant in recent years. This alternative has the advantage of being specific and without risks to the environment. Fungal species of the genus *Trichoderma* have been investigated as biological control agents for more than 70 years. These species are free-living, ubiquitous fungi that interact in the roots, soil and leaf environment, which act as biological control agents and whose antagonistic properties are based on the activation of very diverse mechanisms. Not so much work has been done in this area of research particularly on such an important crop and pathogen that are already gaining attention in the study area.

MATERIALS AND METHODS

Isolation of the fungal pathogen and the biocontrol agents

The pathogen, *Sclerotium rolfsii* was isolated from infected Okra plant samples by tissue segment method on potato dextrose agar (PDA) medium amended with chloramphenicol (100 mg/L). The fungus was then purified by single hyphal tip method and maintained on potato dextrose agar (PDA) slants at room temperature (28 ± 2°C) until needed. The colony morphology, number of sclerotia, mycelial compatibility grouping and pathogenicity was performed. The isolate was consistently isolated from all the symptomatic plant samples. The fungal colony showed characteristic dense, aerial, fluffy, whitish, cottony mycelia with globoid sclerotia after 12–15 days of inoculation.

The biocontrol agent, ***Trichoderma viride*** and ***T. harzianu****m* cultures were obtained from the rhizosphere soil samples collected from the Teaching and Research Farm Field. Two *Trichoderma* species viz., *Trichoderma viride* and *Trichoderma harzianum* were isolated by soil dilution technique (Johnson and Curl, 1972) on *Trichoderma* specific medium. The colonies were identified by comparing with standard taxonomic key for *Trichoderma* identification (Rifai, 1969). The isolates were purified by single spore isolation method and maintained on potato dextrose agar (PDA) slants. The cultures were stored in the refrigerator at 4°C.

Preparation of inoculum

The pathogen was multiplied on sorghum grain for the pot culture experiment by filling 500ml capacity Erlenmeyer flask with 300 g of sorghum grain, moistened and plugged with aluminium foil wrapped cotton wool. The flask was sterilized in an autoclave at a pressure of 1.4 kg/cm^{-2} for 15 minutes. A 5mm-mycelia disc from the periphery of a 7-day-old culture of *S. rolfsii* was then inoculated onto the grains. The flask was then incubated at room temperature for 12-15 days before use.

Five millimeter mycelia disc from five-day-old pure culture of each *Trichoderma* isolates was transferred into 100 ml conical flask containing Potato Dextrose Broth (PDB) and incubated in the dark at 25 ± 2 0C until the entire liquid surface was covered with the hyphal mat. Fifty gram of the freshly harvested hyphal mat of each fungus was measured into 500 ml of sterile water and the mixture was blended with warring blender to produce the inoculum suspension.

Source of Okra seeds

The seeds of Okra variety NHAR 47-4 used for this study was obtained from Premier seed store by Ministry of Agriculture Ilorin Kwara State, Nigeria. The variety is one of the commonly grown in Ilorin and the neighborhood.

Collection and sterilization of soil

Sandy loam soil was collected from the teaching and research farm (TARF) and transported to the screen house the same day. Sterilization of the soil was done using steam heat method. Sterile soil was dispensed, after cooling, into 5 L plastic pots at the rate of 3 kg per pot. Each pot was punctured at the base to allow for easy drainage of excess water.

Setup of pot experiment to determine the effect of biocontrol agents on stem rot disease

Pot culture experiments were conducted in the screen house of the Department of Crop Protection Faculty of Agriculture University of Ilorin, Nigeria to study the influence of antagonists on stem rot disease incidence. Plastic pots of 5 litre capacity and 20 cm-diameter were filled with 3 kg of the prepared sterile soil. After two days, spore/mycelia suspension of the *Trichoderma* isolates was delivered at the rate of 5ml/kg of soil. The pathogen inoculum was applied one week later at the rate of 5g/kg of soil. Three seeds of the okra variety used were sown in each pot after one day of inoculation. Five pot replicates were maintained per treatment. The following treatments were included in the experiment. i) *T. harzianum*, ii) *T. viridae*, iii) *T. harzianum* + *T. viridae*, iv) Mancozeb; and v) pathogen inoculated only (control). The experiment was in form of a completely randomized design (CRD). Light watering was followed after planting which was done in the morning. An alternate day watering was done when there was enough moisture in the soil. Disease symptoms after inoculation were determined by visual observation. Per cent disease incidence was calculated using the formula: Disease incidence (%) = 100 X No. of infected plant /Total no. of observed plants. Disease severity was determined using the modified Shokes et al, (1996) rating scale of 1-5. Plant height, number of leaves, stem diameter were also recorded. Plant height was taken with thread and later measured using meter rule. Number of leaves was counted directly while stem diameter was measured using a venire caliper.

Table 1: Disease severity class and description

Disease Severity Index	Proportion of plant parts affected
1	Healthy (Plant not infected)
2	Lesion on stem only
3	Up to 25% of the plant symptomatic (wilt or dying)
4	26 – 50% of the plant symptomatic
5	>50% of the plant symptomatic

Data Analysis

The data generated was subjected to analysis of variance using R software version 4.12 and the treatment means were separated using the least significant difference (LSD) at 5% level of significance.

RESULTS

The results of the experiment on the response of inoculated and uninoculated potted okra plant to treatments with *T. harzianum* and *T. viridae* is presented in tables 2, 3 and 4. Generally, the treatments had significant effect ($p<0.05$) on the plant height throughout the duration of the experiment. There was significant difference ($p<0.05$) in the number of leaves only at 4WAP. Significant difference was also recorded for the stem diameter at 2, 5 & 6 WAP.

Disease incidence and severity

Percentage disease incidence in treated samples differ significantly ($p<0.05$) from the control. Mean percentage disease incidence for *T. harzianum*, *T. viridae* and *T. harzianum + T. viridae* was 16.667, 33.333 and 16.667 respectively. Even though these mean values appear to be different in magnitude, they were statistically similar. Mancozeb treated samples were not affected by the pathogen (Table 5). There was no significant difference in the disease severity index values ($p>0.05$) in all the treatments compared to the control (Table 5).

Table 5: Disease incidence

Treatments	Disease incidence (%)	Disease severity index
Trichoderma harzianum	16.667ab±28.87	1.333a±0.58
Trichoderma viridae	33.333ab±28.87	1.667a±0.58
T. harzianum + T. viridae	16.667ab±28.87	1.333a±0.58
Mancozeb	0.000b±0.00	1.000a±0.00
Control	83.333a±28.87	4.333a±0.58

Values are means of five replicates ± standard deviation
Mean values followed by the same letter(s) are not significantly different at 5% by LSD

DISCUSSION

Sclerotium rolfsii (Sacc.) is a highly destructive soil-borne fungal pathogen of worldwide significance. It has a wide host range of more than 500 species of plants (Susleendra & Schlosser 1999). This has made its management through the use of fungicides a difficult task. The negative implications associated with the use of synthetic chemicals has made the search for alternative control measures a priority in the recent times. Biological control has been proved to be a promising disease management technology especially against soil-borne plant pathogens.

This study also demonstrate the bio-control property of *T. harzianum* and *T. viridae* against *Sclerotium rolfsii.* in line with the findings of many researchers (Yaqian Li et al; 2016; Chen J et al, 2021; Mohamed Taha Yassin et al, 2022) who reported antagonism of *Trichoderma* spp. against many plant pathogens. The finding of John et al, (2010), that reported T. *viride* as an efficient biocontrol agent for soybean root rot disease caused by fungal pathogens, *Fusarium oxysporum* f. sp. *adzuki* and *Pythium arrhenomanes* was attributed to the ability of *Trichoderma* sp. to parasitize these two pathogenic agents that were killed after 120 h of incubation on dual culture assay. The mechanism of action employed by *Trichoderma* spp. include antibiosis, mycoparasitism, competition for nutrients and space, promotion of plant growth, induced plant defense mechanism and modification of environmental conditions (Druzhinina et al, 2011). At first, they are able to detect plant pathogens through chemotropism and this is followed by complicated biochemical process leading to secretion of hydrolytic enzymes (chitinases and glucanases) which breaks down components that build up fungal cell walls (Qualhato et al, 2013). In his own study, Zhou et al, (2014) revealed that *Trichoderm*a spp. produce koninginins to inhibit the growth of pathogenic microorganisms. This report is supported by Hu et al. (2017) who found koninginins molecules produced by *Trichoderma* spp. which inhibit the growth of phytopathogens; *Fusarium flocciferum* and *Fusarium oxysporum*.

Findings have shown that the components that build up fungal cell walls were hydrolyzed by hydrolytic enzymes (chitinases and glucanases) secreted by *Trichoderma* spp. and this is immediately followed by lysis of the pathogen's cell wall (Lorito et al, 2010) through hyphal penetration by appresorial formation, production of cell wall-degrading enzymes and peptaibols mediated by heterotrimeric G-proteins and mitogen-activated protein kinases and parasitizing pathogen's cell wall content (Druzhinina et al, 2011; Mukherjee et al, 2012).

This study also showed that the *Trichoderma* spp. tested enhanced growth and development and improved tolerance of the treated okra plants to *Sclerotium rolfsii* inoculum. *Trichoderma* spp. have been described as plant symbiont opportunistic avirulent organisms that are able to colonize plant roots by mechanisms similar to those of mycorrhizal fungi and to produce compounds that stimulate growth and plant defense mechanisms (Harman et al. 2004). The root colonization allows the root to explore a bigger region of soil. This enables the plant to uptake more macronutrients and micronutrients in the soil that give advantages to the plant when encountered with other organisms to compete for the minerals or when minerals are depleted (Contreras-Cornejo et al. 2016). These mechanisms could actually have resulted to the improved growth observed in the okra plants and the tolerance shown against infection by *Sclerotium rolfsii*.

CONCLUSION

Farmers still depend on the use of chemical fungicides to control fungal plant diseases. These synthetic chemicals however, have hazardous effects on both the environment and human as well as animal health. The quest for alternative method of control has led to the studies on bio-control agents to replace the chemical fungicides. In this study, *Trichoderma harzianum* and *Trichoderma viridae* have been seen to promote the growth of okra and reduced the incidence of southern blight disease of okra. These findings can be useful to develop locally customized and innovative disease control approach to manage the disease in okra plant. The efficacy of these bio-control agents can be improved by the adoption of refined isolation techniques, use of adaptable formulation and application procedures for field crops in order to meet the growing demand for the food item.

ABSTRACT
Foliar fertilizer is a chemical or natural substance applied directly onto a plant leaves to improve its health and increase fertility. Therefore, this research was carried out to determine the ***influence of foliar fertilizer rate on the growth, fruit yield and nutritional quality of tomato v****arieties. The experiment was conducted at the experimental site of the Department of Crop Production and Soil Science, Ladoke Akintola University of Technology, Ogbomoso, Oyo State, Nigeria. The treatments consisted of Agrolyser Micronutrient Fertilizer (AMF) sprayed at 5 different rates (0, 25, 50, 75, and 100kg/ha) and three (3) varieties (Royal bold, Tina, and Larisa). The 3x5 factorial experiments were fitted into randomized complete block design (RCBD) with three replications. Data collected on growth parameters (number of leaves and plant height) fruit yield and nutrient content were subjected to analysis of variance and means separated using least significant difference at 5% probability level. The results showed that application of foliar fertilizers significantly ($p \leq 0.05$) influenced the growth and yield of tomato compared to control treatment. AMF at 75 kg/ha produced the highest number of leaves, plant height, number of fruits per plant, weight of fruits per plant and fruit yield (kg/ha). The varietal effect significantly influenced the growth, yield and nutritional quality attributes of Tomato. Tina variety gave the highest growth parameters and fruit yield with and without foliar fertilizer applied, although the values obtained was not significantly different from those recorded for Royal bold. Mineral nutrients content of tomato were significantly affected by application of AMF fertilizer rates. AMF at 75 kg/ha has been found as an alternative to recommended level of chemical fertilizer in ensuring optimum performance in terms of fruit yield and nutritional quality of tomato varieties in Ogbomoso. The mineral contenets and nutritional values significantly affected by the variety with Royal bold recording the highest values while Tina recorded the least value. It is therefore recommended that the farmers in Ogbomoso agro-ecological zone could make use of Royal Bold as the best performing variety at 75kg/ha foliar fertilizer application rate.*

INTRODUCTION

Tomato (*Lycopersicom esculentum* L) is a widely grown vegetable in the world because it is recognized as a rich source of vitamins and minerals. Consumption of tomato can prevent several diseases (Willcox *et al*., 2003) because it has anti-oxidants like carotene, phenolic compounds and ascorbic acid (Periago *et al*., 2009). Availability of tomato and other crops at all times cannot be attained without availability of essential plant nutrients (Chen, 2006; Ali *et al*., 2008). Therefore, plant nutrients become essential components of sustainable agriculture. In the same vein, the essential nutrients must be readily available in sufficient and balanced quantities for optimum plant growth and yield. Nevertheless, suitable and balanced combinations of macro and micro nutrients should be considered not only for essentiality of crop growth and yield but also for friendliness of our environment (Chen, 2006). Tomato can be grown in a variety of geographical zones in open fields or greenhouses, and the fruit can be harvested by manual or mechanical means. Under certain conditions (e.g. rejuvenation, pruning, weeding, irrigation, frost protection), this crop plant can be perennial or semi-perennial, but commercially it is considered an annual (Geisenberg and Stewart, 1986).The commercially important tomato fruit can vary in color, size and shape (Vaughan and Geissler, 1997). The fruit contains a large quantity of water, vitamins and minerals, low amounts of proteins and fats, and some carbohydrates. It also contains carotenes, such as lycopene (which gives the fruit its predominantly red color) and *beta*-Carotene(which gives the fruit its orange color). Modern tomato cultivars produce fruits that contain up to 3% sugar of fresh fruit weight. It also contains tomatine, alkaloid withfungicidal properties. The concentration of tomatine decreases as the fruit matures and tomatine concentration contributes to determining the taxonomy of the species.

Ahamad and Jabeen (2005) indicated that foliar nutrition generally increases the grain yield as well as decreases the amount of fertilizers which applied as soil application. Ali *et al.* (2005) reported that foliar spray increased the metabolic activity of plant. Girma *et al*. (2007) found that foliar application is a visible economic way to increase nutrients uptake. Fageria *et al.* (2009) also reported that crops respond to soil applied fertilizers in five to six days, while the response is faster (48 hours) in foliar application. Foliar application increase nutrients uptake at critical growth stages and resulted in enhanced physiological activity leading to increase yield (Kundu and Sarkar, 2009). Nutrient uptake via the foliage may be much faster as compared to soil nutrition (Lester *et al.,* 2006). Foliar nutrient applications can very quickly correct physiological disorders caused by nutrient deficiencies, as well as help to overcome various stress conditions (Franke , 1986). (Fernández and Eichert 2009) noted that one of the traditional applications of foliar application is to correct nutritional deficiencies in plants. The aims of this study are to determine the best tomato variety and appropriate organic foliar spray rate for the cultivation of tomato in the study area.

MATERIAL AND METHOD

The experiment was conducted at the experimental site of the Department of Crop Production and Soil Science, Ladoke Akintola University of Technology, Ogbomoso, Oyo State, Nigeria. Ogbomoso lies on latitude 8^{0}10N, longitude 4^{0}10E and about 382 sea levels. It is located in the Guinea Savanna Zone of South west Nigeria. The temperature of the site ranged from 28^{0} - 32^{0}C with high humidity of about 74% all year round except in January when the dry wind blows from the north. Rainfall distribution is bio-modal and extends for eight to nine month of the year (Olaniyi, 2006).

The 3 varieties of tomato seeds used (Tina, Royal Bold and Larisa) were obtained from Irorun Agbe, Farmer’s center, Ogbomoso, Oyo state. These were planted on the nursery beds. Agrolyser Micronutrient Fertilizer (AMF) was used for higher yield and longer storability on all crops. The land was manually cleared, packing of debris, using of hoe to raise the bed for the sowing of the seeds. Palm frond was used as mulching materials in protecting the seed and seedlings from excess sunlight and predators. The seedlings were raised in the nursery, watered to avoid wilting and transplanted to the permanent site at 4 WAP at a spacing of 50cm y 50cm per bed.

Forty-five (45) beds were manually made. The experimental area was divided into three replicates, with each replicate having 15beds. These were arranged in a factorial experiment and fitted into Randomized Complete Block design with three replications. The bed size is of 1.2m by 1.2m each with the spacing of 50cm within and 100cm between the replicate. Agrolyser Micronutrient Fertilizer (AMF) was applied at different rate of 0, 25, 50, 75, and 100kg/ha on each block by spraying, at flower initiation.

All the plots of the experimental site were subjected to similar activities which includes weeding, staking and transplanting. Transplanting of three varieties of tomato seedlings were carried out onto the field at four weeks after sowing into the nursery. Weedings were done manually, two weeks interval to avoid retarded growth, competition of weeds and to prevent wide spread of diseases to the tomato plant. Staking was done at 6 WAT to help keep plant off the ground while assisting in their upward growth habit.

Data collection commences two weeks after transplanting (WAT) and repeated every two weeks till the tenth week. At each sampling time, data were collected on growth parameters (number of leaves and plant height) and the yield and yield components.

The Number of leaves was counted at each sampling period and recorded. The Plant height (cm) was determined as the distance between the soil surfaces to the tip of the plant while number of Tomatoes

fruits was collected on each plot per plant stand for the tagged plant. The Weight of fruit/plot (g/plot) was obtained by weighing the tomatoes with the sensitive weighing balance (g) per plot. The length and the diameter of the tomato at harvesting were obtained with the use of vernier caliper and recorded. Harvesting of tomato fruit began 8 weeks after transplanting at physiological maturity. The harvested fruits were taken to the laboratory for analysis for the determination of mineral nutrients and proximate contents of Tomato fruits.
Statistical analysis of data collected was carried out using analysis of variance (ANOVA) and mean separated using least significant difference at 5% probability level.

RESULTS

Number of leaves

The number of leaves of tomato increased as the sampling occasions increases with the highest values recorded at 8WAT (Table 1). The variety and application of foliar spray significantly influenced ($p \leq 0.05$) the number of leaves of tomato plants at all sampling occasions. The highest number of leaves (21.00) was recorded at 75Kg/ha of organic foliar spray while the least (17.83) value was obtained for control at 8WAT. Tina variety (21.80) closely followed by Royal bold (18.57) recorded the highest number of leaves while Larisa variety gave the least (16.88) value at 8WAT.
The organic spray rate and variety interaction effect also significantly ($p \leq 0.05$) affected the number of leaves of tomato plants at all sampling occasions. The highest number of leaves was obtained for all the varieties at 75Kg/ha of organic foliar spray with the highest values recorded for Tina and 75Kg/ha organic foliar spray treatment combinations but with no significant difference from that of Royal bold and 75Kg/ha combined treatment effects.

Plant Height

The results of the plant height of tomato is presented in the (Table 2). 75kg/ha application rate recorded the highest plant height while control gave the lowest plant height across all the weeks. There were significant variations in plant height among the treatments. The plant height was at maximum in Royal bold and minimum in Larisa. The interaction of fertilizer rates and varieties significantly increased plant height compared to control, 100kg/ha with Larisa recorded the longest height while Royal Bold at control recorded the least for all the sampling periods.

Number of Flowers and Fruits

The results of Number of flowers and fruits in this study are presented in Table 3. The highest number of flower was found in 75kg/ha application rate, while control, 25Kgha and 50Kg/ha recorded the least value. Tina variety recorded the highest number of flower and fruit while Royal Bold gave the least value. 75kg/ha foliar application with Tina variety produced the highest number of flowers and fruits while Larisa with 25kg/ha recorded the least value.

Fruit Weight, Length and diameter

Weight of fruits, length and diameter is presented in Table 4. Tina gave the highest fruit weight and length while Royal Bold gave the highest fruit diameter. Larisa at 100kg/ha produced the highest number of fruit weight and 25kg/ha gave the least. For fruit length, 100kg/ha gave the highest while 0Kg/ha and 25kg/ha recorded the least value, for fruit diameter 75kg/ha gave the highest value and control the lowest. Royal Bold at 100kg/ha gave the highest fruit weight and control recorded the least value. For fruit length, 75kg/ha gave the highest value, for fruit diameter, 75kg/ha gave the highest and 100kg/ha the lowest. Interactive effect of foliar fertilizer significantly increased the number of fruits weight, length and diameter. At 75kg/ha, Tina recorded the highest value and the lowest 50kg/ha. For fruit weight, 75kg/ha recorded the highest number of fruit length and control gave the least. 75kg/ha recorded the highest value followed by 100kg/ha and the lowest 0kg/ha for fruit diameter.

The mineral nutrient content of tomato is shown in Table 6. At 50kg/ha, K recorded the highest while Mg, P, Na, Fe, Zn, Ca does at 100kg/ha with the least value at control. Larisa gave the highest value for K and P while Tina gave the least. For Mg, Tina gave the highest while Royal Bold gave the lowest. For Na, Fe, Zn, Ca, Royal Bold gave the highest while Tina gave the lowest. Application of foliar fertilizer rates with varieties significantly influenced all the mineral tested except P. 50Kg/ha on Larisa and Royal Bold gave the highest value except for Tina which recorded highest K content at 75kg/ha while control gave the least. For Mg and P content, 100kg/ha on Larisa, Royal Bold and Tina produced the highest value. For Na on Larisa, 50kg/ha gave the highest, 100kg/ha for Fe, Zn, Ca and Fe. On Royal Bold, 50kg/ha gave the highest for Na, 100kg/ha for Fe, Zn, Ca. And lastly on Tina, 100kg/ha gave the highest value of Na, Fe, Zn, and Ca contents.

DISCUSSION

This experiment was set up in order to investigate the influence of foliar fertilizer application of AMF (Agrolyser Micronutrient Fertilizer) on varieties of tomato namely royal bold, Tina, Larisa. The product has a good effect on the plant height and increase in the fruit yield as they had been treated compared to the control level. However, as the experiment is ongoing, there is one known disadvantage about the foliar fertilizer applied to the plant, which is leaf burn. There are signs of visible burns on the leaves after spraying on the leaf area, but not too much as the plant is maturing, and there is no other effect noticed. The results of current experiment showed a significant initial increase in plant height, number of leaves and fruit yield, but at the later stages of the experiment plants were significantly taller, numerous leaves, and the fruit size was increased in (Table 1, 2, 3). Foliar fertilizer rate at 75kg/ha increased the values of the three varieties used in the study. This foliar fertilizer application used reduced protein contents, but increase the mineral and the photochemical contents which could be because of the level of treatments used. Foliar spraying on plant increases the plant growth, especially during fruit set and development, which appears to improve the fruit nutritional quality.

CONCLUSION AND RECOMMENDATION

The result of this studies showed that the treatment used were significantly different for growth parameters and nutritional components. The variety Tina followed by Royal Bold at 75kg/ha gave the highest values in terms of growth, fruit yield and nutritional attributes, while variety Larisa recorded the least values. It is therefore recommended that the farmers in Ogbomoso agro-ecological zone can make use of Royal Bold as the best varieties, with 75kg/ha foliar fertilizer rate, since they both gave the highest values at 75kg/ha rate in the parameters considered.

ABSTRACT
In a landscape, balsam is an ideal choice for beddings due to its beautiful and colourful petals. The experiment was conducted at the Student's Field School Project, Ladoke Akintola University of Technology, Ogbomoso (Latitude 8° 10′ N; Longitude 4° 16′ E; 321 m above sea level) between May and October, 2020, to determine the growth and flowering response of Impatiens balsamina (balsam) to compost rates (0, 5, and 10 t/ha). The experiment was laid out in a completely randomized design with six replicates. Data were collected on plant height, number of leaves, stem girth, number of flowers, flower yield, pod weight, seed weight and percentage seed to pod weight. Data collected were subjected to analysis of variance (ANOVA) using GENSTAT 12th edition, and significant mean separation was done using least significant difference (LSD) at 5% probability level (Wahua, 1999). The results of the experiment showed that application of 5 t/ha compost to hybrid balsam increased plant height and flower yield more than other treatments. Furthermore, balsam that received 5 and 10 t/ha produced higher number of leaves, wider stem, more pod and seed weight than 0 t/ha compost. In conclusion, application of compost significantly improved growth and flowering of Hybrid Balsam. 5 t/ha of compost is optimum for balsam production.
Keywords: *balsam, organic fertilizer, compost*

INTRODUCTION

Organic fertilizers are sustained sources of nutrients due to slow release during decomposition. They enhance the natural soil processes, which have a long-term effect on soil fertility (Rajeev, 2012). Organic fertilizers are rich in nutrients mainly derived from animal manure and crop straws, which are agricultural waste. Commonly used organic fertilizers include compost, composted animal manure and food processing wastes. (Ojo *et al*., 2021). It has been demonstrated that use of organic inputs such as compost, crop residues and manures have great potential for improving soil productivity and plant yield through improvement of the soil as well as nutrient supply (Dauda *et al*., 2008). Compost is useful as soil amendment that provide stable carbon as well as slow-release nutrients which in turn can lead to soil quality improvement, better crop performance, fewer undesirable environmental impacts (WSU, 2021).

Impatiens balsamina commonly called Balsam, belong to the family of Balsaminaceae (Ojo *et al*., 2021). It is an annual plant growing to 20 - 75 cm tall, with a thick, but soft stem. The leaves are spirally-arranged, 2.5-5 cm long and 1-2.5 cm broad, with a deeply toothed margin and 2.5 - 5 cm diameter. Balsam is pollinated by bees, other insects and by nectar-feeding birds. *Impatiens balsamina* is widely cultivated as an ornamental for it attractive flowers, the flowers are pink, red, mauve, lilac, or white. It is used for ornamental purposes such as bedding and pot plant. It has medicinal purposes e.g anti- cancer (Annabelle *et al*., 2013). It is an ornamental plant (Gardeners, 2017) which is ideal for containers, hanging baskets, and beds. Balsam has high nectar production which attracts most insect pollinators, especially bees (Greenwood *et al*., 2017). Its green seed pods, seeds, young leaves and shoot are edible (Balogh, 2008). The flowers can turn into a jam or a parfait. The oil from the seeds can be used as ailment and it is good for lamp oil. It is also used for nail and skin painting (Ojo *et al*. 2021)

Compost improves soil fertility, soil texture and provides nutrients to crop. However, the use of compost among flower growers is low compare to the use of synthetic fertilizer. Hence, the study of this experiment was to provide information that will support the production of Balsam with respect to compost. The objective of the study was to determine the growth and flowering response of *Impatiens balsamina* to different compost rates.

MATERIALS AND METHODS

Pot experiment was conducted between May and October, 2020 at Student Field School, Ladoke Akintola University of Technology, Ogbomoso, Oyo State (Latitude 8° 10´ N; Longitude 4° 16´ E; 321 m above sea level) and is located within Southern Guinea - Savannah agro-ecological zone of Nigeria with two distinct bimodal seasons. Soil samples were collected for physical and chemical analysis (Table 1). Compost was derived from poultry manure, wild sunflower (*Tithonia diversifolia*) and woodash mixed in the ratio 3:3:1 (v/v/v) respectively. The compost was turned and watered weekly for 6 months. Nutrient analysis of compost was also done (Table 1). Prior to the land preparation, soil samples were sifted by a 2-mm sieve. Seeds were sown in a seedling tray using drilling method at 2 mm depth, 2 cm spacing at inter-row and 1 cm intra-row were used. The trays were kept under a natural shade of *Psidium guajava* tree. Seedlings emerged 3 days after sowing. The seedling pots were draped over with net to avoid insect pest attack. Perforated 5 kg pots were filled with well mixed sifted soil sample and a well cured Tithonia based compost at the rate equivalent to 0 t/ha (no manure), 5 t/ha (11.16 g) and 10 t/ha (22.32 g). Transplanting was done three weeks after sowing at one seedling/pot. The pots were arranged in a completely randomized design with six replicates. Factor considered was compost at the rate of 0, 5 and 10 t/ha. Data collection began a week after transplanting (WAT) at a week interval for 8 weeks. Data were collected on plant height, number of leaves, stem girth, number of flowers, flower yield, pod weight, seed weight, percentage of seed to pod weight. Data collected were subjected to analysis of variance (ANOVA) and correlation using GENSTAT 12th edition (commercial version) while significant mean separation was done using Least significant difference (LSD) at 5% level of probability.

RESULTS

Growth parameter

The plant height of balsam was affected by the application of compost. At 5, 7 and 8 WAT, plant height of Balsam was highest with the application of 5 t/ha compost, followed by 10 t/ha and the shortest was recorded for balsam with no fertilizer (Figure 1). From 3 to 8 WAT, balsam treated with 5 and 10 t/ha compost produced highest number leaves than control. However, there was no significant difference in the production of leaves from balsam treated with 5 and 10 t/ha compost (Figure 2). In Table 2, stem girth of balsam was significantly affected by the application of compost. From 5 to 8 WAT, balsam applied with 5 and 10 t/ha had widest stem when compared with balsam with no compost.

Reproductive parameter

Number of flowers was higher in balsam that received 5 and 10 t/ha compost when compared with control (Figure 3). Flower yield and pod weight of balsam was highest with the application of 5 t/ha compost, followed by 10 t/ha and the least was recorded for balsam with no compost (Figures 4 and 5). Conversely, seed weight per plant was higher in balsam treated with 5 and 10 t/ha compost when compared with no compost (Figure 6). The percentage of seeds extracted from pods of balsam treated with 5 and 10 t/ha compost was higher (7.4 and 8.3 % respectively) than no compost (3.2%) - Figure 7. The growth parameter measured had positive and significant correlation with reproductive parameters (Table 3). Number of leaves had positive and significant correlation with total number of flowers, flower and seed weight. This shows that growth parameters had direct and significant relationship with reproductive parameters.

DISCUSSION

Plant response to compost treatment is highly dependent on the source, composition and the quantities of compost utilized (Grigatti *et al*., 2007). It was observed that plant height, number of leaves and stem girth were enhanced in balsam treated with compost. This is similar with the findings of Ojo *et al*. (2021) on marigold response to compost application. The plants growth showed better performance where compost quantity was maximum, which was in accordance with the studies of Babajide *et al*., (2008) and Akanbi *et al*., (2007) which stated that plant growth increased with increase in rate of compost.

Adequate nutrient availability ensures improved crop growth and yield performances. The relationship between growth parameters and yield was significant and positive showing that yield parameter is dependent on growth performances. (Ojo *et al*., 2023). This study indicated that compost improved the flowering, pods and seeds weight of balsam than untreated balsam due to decomposition of organic materials that would provide additional nutrients to the growing medium, which may lead to higher uptake of nutrients by the crop and subsequently high yield (Shaheen *et al*., 2007, Skokalu *et al*. 2017).

CONCLUSION AND RECOMMENDATION

The study concluded that compost application to Balsam is necessary. 5 t/ha compost application is optimal for balsam growth and flowering. Application of 5 t/ha compost is recommended for balsam production.

ABSTRACT
The study investigated the effect of varying rates of biochar and goat manure mixture and cutting stages on the leaf area index and dry matter yield of Panicum maximum in the Sahel Savannah region of Nigeria. The experiment was laid in RCBD with three main plots; 3t/ha (1.5 t/ha biochar + 1.5 t/ha goat manure), 6t/ha (3t/ha biochar + 3t/ha goat manure) and 9t/ha(4.5t/ha biochar + 4.5t/ha goat manure) and three subplots (6, 8, and 10 weeks after planting). The result showed that the varying rates of biochar/goat manure had a significant effect on the LAI but not on the DMY. The cutting stages had significant effect on the LAI and DMY. It was concluded that Panicum maximum cultivated with 9t/ha biochar/manure mixture and harvested at 10WAP produced the closest canopy and optimum dry matter yield. It was therefore recommended that farmers in this part of Nigeria should cultivate Paicum maximum using combination of biochar/goat manure at 9t/ha for higher LAI and DMY which is an indication of forage productivity.

INTRODUCTION

Paucity of feed is a major challenge facing livestock productivity in Nigeria (Babayemi, 2006) as feed accounts for as feed accounts for 70-75% of the total cost of production. The Sahel Savannah region of Nigeria is known for high livestock population in Nigeria (FAO 2017). This higher livestock population is threatened by several factors such as low pasture productivity as a result aftermath effect of climate change, farmers/herders clash, armed banditry amongst other menace (Aruwayo *et al*., 2021). Tropical soils are characterized by low nutrient status which results in production of forage with poor nutrient value (Aregheore, 2002). Biochar and goat manure are organic soil amendments that have been shown to improve soil fertility and crop productivity (Andre et al., 2020). Though there is a paucity of information on the use of biochar and goat manure mixture on forage grass productivity, previous studies have shown that the combined application of biochar and inorganic fertilizer significantly affected phenological variables and agronomical parameters (Buli et al., 2022). Additionally, the effect of biochar on soil with varying doses of nitrogen fertilizer has been studied, and different nitrogen fertilizer application rates have been found to affect agro-physiological performance and productivity of maize (Gudade *et al*., 2022). A review on the effects of biochar on soil fertility and crop productivity suggests that biochar has the potential to improve the productivity of arid regions by increasing the water holding capacity and reducing infiltration rate (Andre *et al*., 2020). Furthermore, goat manure treatments have been shown to significantly increase the yield of grasses, the rate of application and type of manure have also been found to affect the forage dry matter yield of *Panicum maximum* (Dele *et al*., 2017). The results of this study will provide valuable information on the potential of biochar and goat manure mixture application and harvest stages on the LAI and DMY of *Panicum maximum* in the Sahel Savannah region of Nigeria.

MATERIALS AND METHODS

Experimental site

The experiment was conducted at the experimental field of the Prof Lawal Abdu Saulawa Livestock Teaching and Research Farm, Federal University Dutsin-Ma, Katsina State, Nigeria. Located on Latitude $11^0$9'45"N, and Longitude 07 ^{0} 38' E, at an Altitude of 610m above the sea level, along Kankara road is characterized by a defined wet and dry season. Wet season starts from early June to late September while the dry season is from September to June. The total annual rainfall ranges from 1110-1580mm with a long term average of 1058.60mm. Maximum air temperature of 28.25^0C were recorded in September and minimum air temperature of 23.35^0 C in September with relative humidity of approximately 68% during the rainy season (MSGRPF, 2023).

Soil Samples of Experimental Site

Soil samples was collected for nutrient analysis from the experimental site with the aid of Soil auger at four corners and center of the plots at 0-30cm depth to make a composite for soil analysis at the beginning of experiment so as to ascertain the level of nutrient in the soil as well as determining the nutrient requirement. The soil sample was analyzed for physical and chemical properties as described by A.E.S (1998). The analysis was carried out at the chemical laboratory of the Department of Soil Science, Faculty of Agriculture, Ahmadu Bello University, Zaria. The soil, at 0-15cm consist of 28% clay, 26% silt and 46% sand which is classified as being loamy soil. The soil is slightly acidic with pH (6.36) and of moderate Organic carbon (0.58%). The total nitrogen (0.18%) and available phosphorus (4.53ppm) were low. The exchangeable cations, Ca^{2+}, Mg^{2+}, K^+ were low to moderate in the soil while Na^+ was of moderate status.

Land Preparation and Experimental Design

A gross land area measuring 9m×9m was used for the trial. The land was cleared and seed beds were prepared to meet a better condition for early establishment of seedlings. The experiment was laid out in a randomized complete block design (RCBD) with 3x3 factorial arrangements, replicated three times. 3 levels of biochar/goat manure (3, 6 and 9 t/ha) were the main plot factors and 3 cutting stages (6, 8 and 10 WAP) were the sub-plot factors. Forage samples cut at each stage of harvest was bulked, and sub-samples analyzed for proximate composition. The analysis was carried out at the Chemical Laboratory, Department of Animal Science, Ahmadu Bello University Zaria.

Biochar/goat manure preparation and application.

Commercial biochar made from tree was purchased from the seller in Dutsin-Ma market. The biochar was made into powder form by pounding, using motar and pestle, Water was sprinkled to reduce dusting. Digital weighing scale was used to measure the biochar before application. Goat manure was sourced from the goat unit of the Professor Lawal Abdu Saulawa Livestock Teaching and Research Farm, Federal University Dutsin-Ma. The biochar and goat manure mixture were applied at the rate of 1:1 with Treatment 1 (3t/ha), Treatment 2 (6t/ha) and Treatment 3 (9t/ha). Each treatment was replicated three times making a total of nine (9) sub-plots. Biochar and goat manure mixture were applied to the experimental plots, incorporated into the soil using hoes three (3) weeks before transplanting, and allowed to rest for proper mineralization. Seed of *Panicum maximum* was sourced from the Seed Store of the National Animal Production Research Institute (NAPRI), Shika, Zaria. The seed was treated against insect attack using insecticide (Apron plus) at 5g/kg before planted in the nursery, where they were raised to seedling before being transplanted to the experimental field at three weeks after nursery establishment at a spacing of 50 x 20cm inter-row and intra- row space respectively, Weeds were kept under control throughout the experimental period.

Chemical Composition of goat manure

Goat manure was analyzed for its chemical composition in order to determine the nutrient content. The result showed that the manure contained 3.95% total nitrogen (N), 0.85% phosphorus (P). 24045.73mg/kg 4900.10mg/kg potassium (K) and micro minerals with 2892.5mg/kg iron (Fe), 217.5mg/kg manganese (Mn), 63.00% copper (Cu), and 350.00% zinc (Zn). This result indicates that goat manure is relatively nutrient loaded and is one of the organic manure of animal origin that can be used for soil amendment.

Sample Collection and Preparation

Samples of *Brachiaria ruziziensis* harvested at 6, 8 and 10WAP were oven dried, milled and subjected to laboratory proximate analysis according to the procedure of (AOAC 2006). The analysis was conducted at the biochemical laboratory, Department of Animal Science, Ahmadu Bello University Zaria.

Statistical analysis

All data collected were subjected to two-way analysis of variance (ANOVA) using general linear model (GLM) procedure of SAS (2005). Significant (P<0.05) different between treatment means were compared using Duncan Multiple Range Test, (Duncan 1995) of SAS package.

Table 1: Effect of biochar/goat manure mixture and stages of cutting on the Leaf Area Index and Dry Matter Yield of *Panicum maximum*

BC/GM	LAI	DMY
9	3.85[a]	8.78
6	2.84[b]	8.51
3	2.96[b]	7.61

10	5.34[a]	16.27[a]
8	2.71[b]	6.40[b]
6	1.59[c]	2.23[c]
SEM	0.46	1.62

[abc]Means with different superscripts along the columns differ significantly (P<0.05). BC= Biochar, GM= Goat Manure, SEM= Standard Error of the Mean

Leaf Area Index (LAI) is an important factor in the dry matter accumulation and yield of *Panicum maximum*, it is the ratio of the total leaf area to the ground area covered (Jonathan et al 2017). In this study, the LAI was higher (P<0.05) in grass fertilized with 9t/ha biochar/goat manure and harvested at 10WAP this implies that the LAI increased as the rate of manure application increased and the harvest stage advanced. This could be as a result of essential nutrient present in the combination with adequate moisture, thereby increasing the root absorption, net assimilation rate (NAR), relative growth rate (RGR), maximum light interception increased LAI, high rate of photosynthesis and dry matter accumulation as the plant pass through the growth stages (Gomez, *et al*., 2012). The DMY observed in this study as affected by manure rate is lower than what was reported by (Dele, 2018). This variation could be as a result of different ecological zone or the inherent soil fertility of the experimental areas. The result of the DMY as affected by the rate of biochar/goat manure application was not (P>0.05) significant but the DMY at 9t/ha was 15% higher when compared with the 3t/ha application rate. However, the stage of harvest had a significant (P<0.05) effect on the DMY with the 10WAP producing the highest (16t/ha) DMY. This could be as a result of higher LAI index at this stage, as it has been established that the relationship between the LAI and DMY is directly proportional (Shuaibu *et al* 2018). This is within the range of DMY/ha reported by (Akinola, 2018, Jimoh, 2019, and Idowu, 2021) during separate studies on the DMY of *Panicum maximum.*

CONCLUSION

It was concluded that application of biochar/goat manure at 9t/ha and harvested at 10WAP produced forage with high productivity in terms of LAI and DMY. It was therefore recommended that livestock farmers in the Sahel Savannah region of Nigeria cultivate Panicum maximum using biochar/goat manure at the rate of 9t/ha and harvest at 10 WAP for a higher LAI and DMY for enhanced livestock productivity.

ABSTRACT

In vitro experiments were conducted to evaluate the efficacy of three compost fungi (Trichoderma sp., Aspergillus niger and Aspergillus flavus) isolated from bio-enriched composted cow dung against Fusarium oxysporum f. sp. lycopersici. The experiment was laid out in a completely randomized design, consisting of five treatments, replicated five times. The treatments consisted of Fusarium oxysporum f. sp. lycopersici (Fol) + Trichoderma sp.), Fol + Aspergillus niger), Fol + Aspergillus flavus), Fol + fungicide (Contap Plus®) and Fol only (control). Data on radial growth (RG) and percent growth inhibition (GI) of the five treatments were measured at 3, 5 and 7 days after inoculation and subjected to analysis of variance, and treatment means were separated using LSD at P≤0.01. Trichoderma sp. significantly exhibited lower RG at 3 5and 7 DAI (1.22cm; 2.28cm; 2.32cm) than Aspergillus flavus and Aspergillus niger. Highest growth inhibition (GI) was recorded on Trichoderma-amended plates, where 31.1%, 32.3% and 39.4% were recorded at 3, 5 and 7 DAI, respectively. This was followed by Aspergillus flavus and Aspergillus niger, respectively. Least GI was found were Fusarium oxysporum f. sp. lycopersici was cultured alone as control treatment. Fusarium oxysporum f. sp. lycopersici is effectively suppressed by Trichoderma spp. isolated from bio-enriched composted cow dung and could be subjected to screenhouse and field studies to further ascertain its efficacy in managing tomato wilt caused by Fusarium oxysporum f. sp. lycopersici.

Keywords: *Aspergillus sp., Fusarium oxysporum f. sp. lycopersici, percent growth inhibition, radial growth, Trichoderma sp.*

INTRODUCTION

Tomato wilt caused by *Fusarium oxysporum* f. sp. *lycopersici* is a soil-inhabiting fungus. It is one of the most important diseases highly destructive both in greenhouse and field on tomato in many warm regions of the world (Thanh *et al*., 2009). It causes 10-50 % yield loss (Adebayo and Ekpo, 2004), and up to 80% loss in severe cases (Malhotra and Vashistha 1993). The occurrence of the disease on tomato in Nigeria was first reported in Kaduna (Adebayo and Ekpo, 2007). The disease is endemic in the savannah areas of Nigeria (Erinle, 1981). The pathogen can survive long periods in soil through the formation of certain resistant structures (Blum and Rodriquez-kabana, 2004), thus making management difficult.

Resistant cultivars had been the most effective and economical means of controlling Fusarium wilt of tomato (Adebayo and Ekpo, 2004). However, the occurrence and development of new pathogenic races often caused breakdown of resistance in the introduced resistant varieties within a few years of its commercialization. Several measures including the use of resistant varieties Attitalla *et al*., 2001), cultural practices pesticides (Song *et al*., 2004) had been attempted to control Fusarium, but losses are still substantial (Khaleed *et al*., 2007). There are no commercially acceptable cultivars with adequate resistance to all races of Fusarium wilt pathogen (Attitalla *et al*., 2001). The use of pesticides in the control of Fusarium wilt of tomato is not encouraged due to high cost of pesticides and environmental implications arising from its usage (Nwanguma *et al*., 1999). This necessitated the search for other eco-friendly options.

MATERIALS AND METHOD

The experiment was laid out in a complete randomize design (CRD) to determine the effect of fungi isolated from cow dung-based compost on radial growth and inhibition of *Fol* the incitant of Fusarium wilt of tomato. It consisted of five treatments: *Fusarium oxysporum* f sp. *lycopersici* (*Fol*) + *Trichoderma* sp. (T1), *Fol* + *Aspergillus flavus* (T2), *Fol* + *Aspergillus niger* (T3), *Fol* + CONTAP PLUS® (T4) and control (T5). All treatments were replicated five times. The experiment was conducted at Plant Pathology Laboratory of the Department of Crop Protection, Bayero University Kano. The bioassay started from June and lasted to August, 2018. The objective of the experiment was

Isolation and Purification of the test pathogen

Fusarium oxysporum f.sp. *lycopersici* was isolated from diseased tomato plant. Disease samples were rinsed in sterile distilled water three times and blot dried and plated on Petri dish containing potato dextrose agar (PDA) amended with Chloramphenicol and incubated at 25^0C for 7days. The fungus was sub cultured and was incubated at 38 ± 2°C for 10 days to ensure development of macro and micro conidia. The hyphal tip showing reddish purple colour and pinkish white mycelium was taken using sterilized needle. The colony was then sub-cultured to obtain pure cultures following the procedures of Booth (1977). The pure culture was then grown on PDA slants and preserved at room temperature (38 ± 2°C) as stock culture.

Isolation of Fungi from Bio-enriched Cow dung and Preparation of Bio-enriched Cow dung Extract

Three fungi (*Trichoderma, Aspergillus niger, A. flavus*) isolated from Composted cow dung were obtained from the Pathology Lab of the Department of Crop Protection, Bayero University Kano. Bio-enriched cow dung extract was prepared according to the procedures described by Weltzien (1991). One liter of water was added to 500g of the vermicompost and was kept in a 5L plastic bucket. The mixture was stirred for 5-10 minutes every day using stirring rod and allowed to ferment for seven days to enhance disease suppression as described by Hmouni *et al*. (2006). The compost extract was then filtered with two layers of Muslin cheese cloth to remove large particles and used as bio-enriched cow dung extract for the laboratory bioassay.

***In vitro* Bioassay of the Fungi isolated from Bio-enriched Compost**

Dual culture bioassay was used to determine the effects of the compost fungi on radial growth and percent inhibition of a fourteen day-old culture of *Fusarium oxysporum* f sp. *lycopersici*. A 6mm plug of the young culture of test pathogen and antagonistic fungi were placed 3 cm apart near the edge on the surface of PDA medium for each antagonist and test pathogen. The activities of the compost fungi against *Fol* were studied on the Petri dishes incubated at room temperature ±38°C under continuous light. Data on radial growth and growth inhibition were assessed on the 3, 5 and 7 days after inoculation. The measurement of the radial growth of the pathogen was done using a Vernier caliper in the morning at 9.00 O'clock. The average of the measurements was used to calculate the percent inhibition rate according to the formula used by Rini and Sulochana, (2007) as Follows: PGI = [(C- T) /C] X 100. Where PGI= Percent growth inhibition C= Radial growth of the pathogen in control plates (cm), T= Radial growth of the pathogen in treated plates (cm). Data collected were statistically analysed using GenStat Release 7.2 DE (PC/Windows XP) Copyright 2007, Lawes Agricultural Trust (Rothamsted Experimental Station) and treatment means were separated using LSD at 5% level of significance.

Efficacy of fungi isolated from bio-enriched cow dung on radial growth of *Fusarium oxysporum* f. sp *lycopersici*

Table 1 shows the effect of three fungi isolated from bio-enriched cow dung at 3, 5 and 7 days after inoculation. Least radial growth of the pathogen was recorded on plates containing *Fol* + CONTAP PLUS than the other treatments. The average radial growth (RG) of the pathogen at the three inoculation periods were 0.20, 0.40 and 0.56 cm at 3, 5 and 7 DAT, respectively. At 3 DAI *Fol* + *Trichoderma* sp. (1.22cm) significantly exhibited lower RG than *Fol* + *Aspergillus flavus* (1.46cm) and *Fol* + *Aspergillus* niger (1.50cm) which showed statistically similar radial growth. *Fusarium oxysporum* f. sp. *lycopersici* culture alone recorded longer RG (1.77 cm) compared to the other treatment. Similar observation was made at 5 and 7 DAI, where *Fol* + *Trichoderma* sp. had the least RG of 2.28 cm and 2.32 cm, respectively.

Efficacy of fungi isolated from bio-enriched cow dung on percent growth inhibition of *Fusarium oxysporum* f. sp. *lycopersici*

Effect of compost fungi on growth inhibition is presented in Table 2. There were significant differences between the treatments at 3, 5 and 7 DAI. Contap Plus (Fungicide) recorded highest percentage inhibition compared to the other treatments. Among the compost fungi, highest growth inhibition (GI) was recorded on *Trichorderma*-amended plates, where 31.1%, 32.3% and 39.4% were recorded at 3, 5 and 7 DAI, respectively. This was followed by *Aspergillus flavus* and *Aspergillus niger*, respectively. Least GI was found were Fusarium *oxysporum* f. sp. *lycopersici* was cultured alone as control treatment.

DISCUSSION

This experiment showed that *Trichoderma* spp has antagonistic effect against *Fol* and therefor inhibited the growth of the test pathogen. Several researchers have reported the ability of *Trichoderma* spp. to suppress the growth of soilborne phyto-pathogenic fungi, especially *Fol* (*Chen et al*., 2021; Debbi et *al*., 2018; Nashwa *et al*., 2019; Taghdi *et al*., 2015). Mycoparasites has been widely used as antagonistic fungal agents (Elad and Chet, 1983). Several *Trichoderma* species are considered to be stoutly antagonistic to other phytopathogenic fungi. Their different mechanism of parasitism to other phytopathogenic fungi occurs by various mechanisms such as competition, antibiosis, mycoparasitism, induced resistance and inactivation of pathogen's enzyme (Benitez *et al.,* 2004).

CONCLUSION AND RECOMMENDATION

Fusarum oxysporum f. sp. *lycopersici* is effectively suppressed by *Trichoderma* spp. isolated from bio-enriched composted cow dung and could be subjected to screenhouse and field studies to further ascertain its efficacy in managing tomato wilt caused by *Fusarium oxysporum* f. sp. *lycopersici*.

ABSTRACT

In this study, the effect of rates of sawdust (0g, 80g, 120g and 160g) on soil chemical properties and the performance of Groundnut (Arachis hypogaea L.) was investigated for a period of 15 weeks. The experiment was laid in a Randomized Complete Block Design (RCBD) and replicated 3 times. 48 polybags of sandy topsoil were prepared and 0g (control), 80g, 120g and 160g of sawdust were incorporated into the 10kg soil contained in each of the polythene bags. Then, 3 groundnut seeds were sown on the same day and the seedlings were thinned to one exactly 2 weeks after planting (2WAP), while data were collected weekly on parameters such as germination percentage, plant height, number of leaves, leaf area, number of pods, number of seeds, weight of pods and weight of seeds. Data collected were subjected to analysis of variance (ANOVA) using personal computer software packages SPSS version 20.1. Significant treatment means were compared using the Duncan multiple range test ((DMRT)) at $P \leq 0.05$. Results showed that increasing rates of sawdust increased the germination percentage and plant height of groundnut except at 6WAP. Leaf area increased from $8.918mm^2$ to $9.477mm^2$ at 120g, number of leaves was not significantly ($P \leq 0.05$) increased, number of seeds increased from 19 at 0g to 21 at 160g of sawdust application, seed weight increased from 20.0g at control to 22.3g at 160g but the number of pod and weight of pod was not significantly ($P \leq 0.05$) increased when compared to control. The sawdust rates (80g, 120g and 160g) incorporated in the soil significantly decreased the soil pH range but still within a pH range of 6 and 7, required for groundnut cultivation. It also decreased the available phosphorus and potassium content in the soil which resulted in the reduced number of pods and weight of pods of the groundnut plant. In conclusion, sawdust as a soil amendment significantly increased the number of seed and weight of the groundnut seed but did not significantly increase the number of pods and weight of pods of the groundnut plant.

INTRODUCTION

Groundnut (*Arachis hypogaea* L.) or peanut as it is sometimes referred to is grown in a commercial scale in the Northern region of Nigeria. Nigeria is the 4th highest producer of groundnut in the world and groundnut is the 13th most important food crop and 4th source of edible oil and protein in the world according to Food and Agricultural Organization (FAO,1994). Groundnut is useful to humans and animals as food. A 100 grams of raw peanuts is estimated to contain: 567 Calories, 25.8g Protein, 49.2g Fat (Saturated - 6.28g, Monounsaturated - 24.43g, Polyunsaturated - 15.56g), 16.1g Carbohydrate, 4.7g Sugar, 8.5g Fiber and 7% Water (Toppo, 2021). It is useful in farm practices to help replenish nutrients in the soil due to its ability as a leguminous plant to fix atmospheric nitrogen in soil (Brady, 2017). Sawdust is a waste material generated from the timber industry and is composed of fine wood particles. It is a common and affordable organic material that lay waste in several sawmills, dumpsites, and parts of Nigeria (Owoyemi *et al.,*2016). Hence, the need for its usefulness and ability to influence plant growth should be investigated to determine to what extent it imparts the soil and improves the vegetative growth of crops and crop yield.

Sawdust contains 40% lignin and 60% cellulose with a little bit of waxes, resins and oils mixed in. It is low in nutrient density, only containing 0.048% nitrogen (N), 0.007 % phosphorus (P), 0.017% potassium (K) and 0.106% calcium (Ca) which varies depending on the wood the sawdust comes from. Also, the physical properties of sawdust such as water content (10.8%), apparent gravity (0.14%), porosity (84%), water retention capacity (50%), are favourable factors that improve soil properties for plant growth and development (Terazawa *et al*.,1999). Donald (1969) reported a decrease in nitrogen in soils mixed or mulched with sawdust.

Sawdust decomposition depends on the complete hydrolysis of lignin and cellulose by ligninase and cellulase, respectively (Ververis et al., 2007). Sawdust is converted to biofertilizers by composting, which ties up nitrogen for 180 days in soil (Olayinka & Adebayo, 1989). It is a non-degradable organic waste because of its low nitrogen content and high lignin and cellulose content. Studies have shown that sawdust does break down into humus, creates soil structure, increases aeration (porosity and permeability), increases a soil's water-holding capacity, and increases microbial activity after it has broken down. This depends on many factors and may take months to years. Some microorganisms, especially Actinobacteria, effectively decompose sawdust with nitrogen supplementation (Eriksson et al., 1990, Ting et al., 2014).

Soil microbial population was observed to have increased by incorporating sawdust with the soil (White et al., 1959). Researchers have reported the favourable effect that organic growing media (sawdust and Coir) have on plant growth (Maboko *et al;*2003, Tzortzakis and Economakis, 2008), as it increased the porosity and water retention of the growing medium (Hardgrave and Harrisman,1995; Marinou *et al;* 2013). Maboko *et al;*(2013) however reported that organic growing media (sawdust) did not have significant effect on tomato yield. Sawdust applied either as a mulch or mixed with the soil, decreased the nitrate content of the soil (White et al., 1959). The usage of sawdust as a plant growth medium in manufacturing industries is highly recommended due to the positive physical properties of the sawdust such as biodegradability at an acceptable rate, low superficial specific gravity, high porosity, high water retention, moderate drainage and high bacterial tolerance (Maharani *et al;*2010).

MATERIALS AND METHOD

Area of Study

The experiment was carried out in the Faculty of Agriculture, Teaching and Research Farm, Ignatius Ajuru University of Education (IAUE) Ndele campus, Rivers State, Nigeria (latitude 4^0 58' N and Longitude 6^0 48' E).

Sources of Samples and pot preparation.

The sawdust was collected from a Sawmill and a local variety of groundnut seeds was bought from a local market within the community. A digital weighing scale was used to measure the respective weight of the sawdust and applied to the soil in the polythene bag.

48 polybags of width 45cm and height of 27cm were perforated with 10 small holes each to allow easy drainage were made available for the pot. Sandy topsoil (0-15cm) was collected from the demonstration farm weighing 10kg and filled into the polybag up to the height of 25cm leaving a space from the top of about 2cm to allow for the application of water. This was replicated into three.

Experimental treatment design and field layout.

The experiment was laid in a Randomized Complete Block Design (RCBD) and replicated 3 times. The sawdust were measured into the polybag using a digital weighing machine at the rate of 0g, 80g, 120g and 160g. The 0g of sawdust polybag serves as control. On the same day, the polybags were prepared; sawdust treatment was applied and the groundnut seed was sown at 3 seeds per polybag in which the seedling was thinned to one after 14 days.

Collection and arrangement of Data

Data of the plant were collected from the field weekly from the date of planting. Data collected from the field include; Germination Percentage, Plant height, Number of leaves, Leaf area, Number of pod per plant, weight of pod per pot and weight of the groundnut per plant.

Soil samples were collected for laboratory analysis at planting (immediately after application of treatment) and at harvest (immediately after harvesting the plant).

Statistical analysis

The result was subjected to the analysis of variance (ANOVA) using a statistical software, SPSS 20.1 version. Significant treatment means was compared using Duncan multiple range test at P≤0.05.

RESULTS

Germination rate increased with increasing sawdust rate. Table 1 shows control at 87% while 80g, 120g and 160g sawdust rate resulted to 90%, 94% and 96% germination percentage respectively.

Table 1: Influence of sawdust rates on the germination of Groundnut.

Sawdust (g)	germination percentage
0	87%
80	90%
120	94%
160	96%

Increasing rate of Sawdust significantly at P≤0.05 increased the growth rate of the groundnut seedling when compared to the control as shown in table 2 except for week 6. At 3WAP growth increased from 15.21cm for control to 17.48cm for 120g sawdust rate. At 6WAP growth increased from 32.20cm for control to 30.28cm for 160g sawdust rate. At 9WAP growth rate increased from 41.53cm for control to 43.09cm for 10g sawdust rate. At 12WAP growth increased from 71.95cm at control to 77.13cm at 120g sawdust rate. At 15WAP growth increased from 83.28cm for control to 91.27cm for 160g sawdust rate.

Table2: Influence of sawdust rates on the Growth of Groundnut.

		Plant height week after planting			
Sawdust(g)	3WAP	6WAP	9WAP	12WAP	15WAP
0	15.21a	32.20d	41.53a	71.95a	83.28a
80	15.72b	31.72c	43.09d	68.84a	82.58a
120	17.48c	31.50b	42.98c	77.13b	89.88b
160	15.80b	30.28a	42.80b	76.03ab	91.27b
SE	0.047	0.020	0.037	1.505	0.710

Mean with different alphabets in same column are significantly different at P ≤ 0.05 using Duncan multiple range test. WAP=Weeks After Planting. SE=Standard Error.

Leaf area at 120g and 160g sawdust rate resulted to 9.477mm^2 and 9.200mm^2 respectively and exceeded leaf area of control of 8.918mm^2 significantly at P≤0.05 and 80g sawdust rate resulted to 8.558mm^2 leaf area which is below control.

The number of leaves was influenced by increasing sawdust rate which exceeded control;146.917 significantly (P≤0.05) at 120g;161.833 and non significantly at 160g; 147.333.

Table 3: Influence of sawdust rates on the number and area of leave of Groundnut at 8th weeks after planting respectively.

Sawdust(g)	Number of leaves	Leaf area(cm^2)
0	146.917b	8.918b
80	140.167a	8.558a
120	161.833c	9.477d
160	147.333b	9.200c
SE	0.875	0.012

Mean with different alphabets in same column are significantly different at P ≤ 0.05 using Duncan multiple range test, WAP=Weeks After Planting. SE=Standard Error.

Number of pod and pod weight were not significantly increased by sawdust as seen in table 4 while number of seed and seed weight were significantly (P≤0.05) increased by sawdust and exceeded control at 160g. Number of seed increased from 17.8 at 80g to 19.1 at 120g to 21.5 at 160g. Likewise Seed weight increased from 18.4g at 80g to 19.7g at 120g to 22.3g at 160g.

Table 4: Yield of groundnut response to sawdust rates.

	Groudnut Yield Parameters			
Sawdust(g)	Number of pod	Pod Weight	Number of seed	Seed weight
0	24.7c	51.3c	19.3b	20.0b
80	16.2a	43.5a	17.8a	18.4a

SE	0.007	0.005	0.001	0.375	0.001	0.002	0.058	0.270

Mean with different alphabets in same column are significantly different at P ≤ 0.05 using Duncan multiple range test. WAP=Weeks After Planting. SE=Standard Error. Available P= Available Phosphorus. CEC=Cation Exchange Capacity. EC=Bulk density. BS=Base saturation.

At harvest as seen in Table 6, pH was least at 120g; 6.18 but exceeded Control 0g; 6.98 at 80g; 7.11. Application of sawdust did not significantly influence Total Nitrogen was least at 120g; 0.152%, but highest at 80g; 0.215% but at 160g; 0.218% and that exceeded Control 0g; 0.184%. Organic matter increased from 3.019% at Control to 3.990% at 80g, and still exceeded control at 120g; 3.521%, and 160g; 3.663% . Available P was least at 160g; 9.131ppm, highest at 80g; 14.168ppm, and still exceeded Control 0g; 15.386ppm at 120g; 13.673c ppm. Potassium increased with increasing rate of sawdust from 0.008Cmol/kg at 80g, (120g; 0.012Cmol/kg) to 0.014Cmol/kg at 160g but lower than Control 0g; 0.023 Cmol/kg. CEC was least at 120g; 5.676 Cmol/kg and exceeded Control 0g; 6.100Cmol/kg at 160g6.969 Cmol/kg which was not significantly different with 80g; 7.891 Cmol/kg. Bulk density exceeded Control 0g; 65.550μ/cm at 120g; 67.675 μ/cm but least at 80g; 51.128 μ/cm. Base saturation was least at 120g 80g; 96.651% but no significant difference at control 97.358% when compared to 80g; 97.438% and 160g; 97.447%.

DISCUSSION

From the results, the 80g sawdust incorporated in the soil increased pH significantly (P≤0.05) exceeding control but decreased pH at 120g and 160g. Agbim and Adeoye, 1994 have reported that organic wastes incorporated into the soils are capable of increasing the soil pH because they contain exchangeable cations. The Nitrogen was not significantly influenced by sawdust. Although, White et al., (1959) reported that sawdust applied either as a mulch or mixed with the soil decreased the nitrate content of the soil. Whereas Eneje and Ukwuoma, (2005) attributed this to nitrogen immobilization by the sawdust. The sawdust increased the organic matter content of the soil significantly (P≤0.05). Eneje and Ezeakolam, (2009) also reported soil organic matter significantly increased with the application of sawdust as a soil amendment. The Available phosphorus was decreased with increasing Sawdust at harvest but increased with increasing sawdust at planting. This can be attributed to the increased use of available P in soil by the groundnut plant for nodulation and root formation toward harvest. (Sulieman and Tran, (2015) Valentine *et al.,* (2017) already reported that Phosphorus is an essential nutrient used by groundnut plants, especially for nodulation and root development.

Sawdust had no significant difference in K at harvest but resulted in to decrease in K at harvest. However, as sawdust increased, K also increased significantly. This corresponds with Starbuck (1999) report of an increase in the K content of the soil with an increase in sawdust. Sawdust in this study increased the CEC of the soil. Moreover, sawdust as an organic matter will result in increased exchangeable cations. Ayuba et al., (2001) reported that organic matter contains high exchangeable cations. The bulk density of the soil decreased with increasing sawdust. Susan et al. (2020) also reported a decrease in bulk density with increased sawdust. The percentage Base Saturation was not influenced by the sawdust significantly (P≤0.05). However, Awodun (2006) reported an increase in the organic matter, pH, N, P, K, Ca and Mg contents of the soil with the incorporation of sawdust.

This study shows that increasing sawdust rate significantly (P≤0.05) resulted in increased germination percentage, vegetative growth (leaf area, number of leaves and plant height) and the number of seeds and weight of seeds of the groundnut plant. This increase can be attributed to favourable properties such as the bacteria nitrogen-fixing characteristic of the groundnut (leguminous) plant in the soil which supports vegetative growth of plant. Also, as seen in the Table 5 and 6, the sawdust maintained a pH range of between 6 and 7, which is suitable for groundnut cultivation (TIMEIS Project & TIMEIS Project, 2019). However, the Sawdust incorporated in the soil did not significantly increase the number of pods and pod weight. This can be attributed to decreased phosphorus and potassium which is highly required for pod production in groundnut. Baughman *et al,* (2015) reported that groundnut plant requires an adequate level of phosphorus, potassium and other micronutrients and a pH of less than 7.

CONCLUSION.

The sawdust rates (80g, 120g and 160g) incorporated in the soil significantly decreased the soil pH range but still within a pH range of 6 and 7, required for groundnut cultivation. However, it resulted in a reduced number of pods and weight of pods due to decreased soil potassium and phosphorus content required for pod growth and development. Increasing sawdust rates in the soil as a soil amendment did not significantly increase the number of pods and weight of pods of the groundnut plant but influenced the increase in the number of seeds and weight of seeds of the groundnut plant.

ABSTRACT

Marigold (Tagestes erecta L) is a commercially valuable cut flower. The experiment was conducted at the Student's Field School Project, Ladoke Akintola University of Technology, Ogbomoso (Latitude 8° 10′ N; Longitude 4° 16′ E; 321 m above sea level) between March and August 2021 to determine the growth and flowering responses of African marigold to compost application rates (0, 5, 10 and 15 t/ha). The experiment was laid out in a completely randomized design with five replicates. Data were collected on plant height, number of leaves, stem girth, shoot weight and flower yield. Data collected were subjected to analysis of variance (ANOVA) using GENSTAT 12th edition, and significant mean separation was done using least significant difference (LSD) at 5% probability level (Wahua, 1999). The results of the experiment showed that application of compost to African marigold at rates of 5, 10, and 15 t/ha produced more leaves, taller plants and wider stems compared to African marigold treated with no compost. However, there was no significance difference in the shoot weight of marigold treated with 0, 5, 10 and 15 t/ha. The flower yield of plant applied with compost at the rate of 5, 10 and 15 t/ha were similar but greater than the control. In conclusion, application of compost significantly improved growth and flowering of African marigold. 5 t/ha of compost is optimum for marigold production.

INTORDUCTION

Compost as defined by (Paulin and Peter 2008), comprises organic materials that have undergone controlled aerobic decomposition, resulting in relatively stable, nutrient-rich matter. Compost, often referred to as "black gold" in gardening, have a transformative impact on both soil and plants. The diminished soil fertility not only leads to reduced crop yields but also renders crops more vulnerable to pest and disease infestations due to their weakened state (Madeleine et al., 2005). Compost empowers plants with enhanced nutrient access, improved resistance to pests and diseases, and efficient water utilization. It provides nutrients to the soil, improves its water holding capacity, and helps the soil to maintain good tilt and thereby better aeration for germinating seeds and plant root development (Edwards and Hailu, 2011). Therefore, it stands as a cornerstone of sustainable agriculture and a key ally in promoting healthier, more productive plant life. The utilization of compost stands as a pivotal factor in bolstering agricultural productivity and promoting sustainability. Furthermore, it offers a practical solution to the challenges confronting farmers dealing with soil fertility decline.

(Tagestes erecta) belong to the family of Asteraceae. is a genus of herbs, commonly known as marigold, native of Mexico and other warmer parts of America and naturalized elsewhere in the tropics and sub-tropics (Anonymous, 1976). The size of flower may vary from 4 to 6 cm (diameter) (Rajmani *et al*., 2020). The flowers of marigold are deep orange, light orange, golden yellow, bright yellow and lemon yellow in color. Several species are grow in gardens for ornamental purpose and its beauty. The plants are highly useful for suppressing the population of nematodes in the field also for the production of economical yield of better quality of marigold flowers, it is necessary to adopt a proper agro technique by applying important nutrients in mandatory quantity and special horticultural practices (Yadve LP and Bose TK 1993). Obvious varietal difference are found in marigold given that orange marigold has

emerged as rich source of carotenoid including xanthophyll, which is widely used as dietary supplement in the poultry industry to enhance chicken skin color and egg yolk pigmentation (Naik *et al.,* 2004).
Compost enhances soil fertility, improves soil texture, and supplies essential nutrients to crops, its adoption among flower growers remains relatively limited when compared to the widespread use of synthetic fertilizers. The study of this experiment was to provide information on compost rate that will support the production of marigold.

MATERIAL AND METHODS

Pot experiment was conducted between March and August, 2021 at Student Field School, Ladoke Akintola University of Technology, Ogbomoso, Oyo State (Latitude 8° 10´ N; Longitude 4° 16´ E; 321 m above sea level) and is located within Southern Guinea - Savannah agro-ecological zone of Nigeria with two distinct bimodal seasons (Babajide *et al*., 2012). Soil samples were collected for physical and chemical analysis. Compost was derived from poultry manure, wild sunflower (*Tithonia diversifolia*) and woodash mixed in the ratio 3:3:1 (v/v/v) respectively. The compost was turned and watered weekly for 6 months. Nutrient analysis of compost was also done (Table 1). Prior to the land preparation, soil samples were sifted by a 2-mm sieve. Seeds were sown in a seedling tray using drilling method at 2 mm depth, 2 cm spacing at inter-row and 1 cm intra-row were used. The trays were kept under a natural shade of *Psidium guajava* tree. Seedlings emerged 3 days after sowing. The seedling pots were draped over with net to avoid insect pest attack. Perforated 5 kg pots were filled with well mixed sifted soil sample and a well cured Tithonia based compost at the rate equivalent to 0 t/ha (no manure), 5 t/ha (11.16 g), 10 t/ha (22.32 g) and 15 t/ha (44.64g). The pots were organized in a completely randomized design with five replicates, Factor considered was compost at the rate of 0, 5, 10 and 15 t/ha. Data collection began a week after transplanting (WAT) and continued weekly for twelve weeks. Data were collected on plant height, number of leaves, stem girth, shoot weight and flower yield. Data collected were subjected to analysis of variance (ANOVA) using GENSTAT 12th edition (commercial version) while significant mean separation was done using Least significant difference (LSD) at 5% level of probability.

RESULTS

Compost application affects the height of Marigold. From 3 to 6 weeks after transplanting (WAT), Marigold applied with 10 t/ha produced taller plant when compared with 0, 5 and 15 t/ha compost. However, there was no significant difference between marigold that received compost at the rate of 5, 10 and 15 t/ha from 7 to 10 WAT with respect to plant height (Figure 1). From 3 to 8 WAT, marigold treated with no compost produced lowest number of leaves than 5, 10 and 15 t/ha except at 5 WAT where all the treatments had similar number of leaves (Figure 2). Stem girth of marigold was significantly affected by the application of compost. From 7 to 12 WAT, marigold that received 5 t/ha had widest stem, followed 10 and 15 t/ha and the thinnest stem was recorded for marigold with no compost except at 8 and 9 WAT (Figure 3). Shoot weight of marigold was similar in all the treatments applied (Figure 4). Marigold treated with 5, 10 and 15 t/ha compost had higher flower yield compared with no compost. However, there was no significance difference in the plant that received 5, 10 and 15 t/ha compost (Figure 5).

DISCUSSION

The soil used for this experiment was sandy clay and low in N, P, and K, along with compost low in nitrogen and potassium but high in phosphorus and calcium. Compost positively influenced African marigold's growth and flowering, in agreement with previous research by Yamato et al. (2006) and Ibrahim et al. (2004), who reported that compost application to soil is important to improve agricultural crops and amend soil deficiency. It was observed that plant height, number of leaves, and stem girth were enhanced in marigold treated with compost. This is similar with the findings of Ojo *et al.* (2021). Marigold applied with compost gave higher yield of flower than no compost. This observation was in accordance with the report of Ojo *et al*, (2021) who reported that higher application of compost to marigold was more effective for increasing number of flower yield and along with reducing the crop duration by early flowering. The result obtained could be attributed to compost application that help plant to produce more photosynthate that were used by the plant production of higher yield of flower. Marigold treated with compost had the highest shoot weight, possibly due to the calcium content in the compost, in line with Lucas da Silva *et al.* (2016), who reported that higher dry mass of shoot and root of common beans grown with high calcium concentration.

CONCLUSION

The result from the experiment showed that compost application supports growth and flower yield of African marigold. Compost application at the rate of 5 t/ha is optimum for the growth and flower yield of marigold. Application of 5 t/ha compost is recommended for African marigold production.

ABSTRACT

Land use and soil management practices are the keys to improving the SOC of the soil and maintaining sustainable agricultural production. This research was conducted in Ogbomoso North, Orire and Surulere Local Government Areas of Oyo State to assess the soil organic carbon stock and other soil properties of Cashew (Anarcadium occidentale L.) under plantation crops. Three farms noted for cashew plantations were visited and in each village, three farms planted each with cashew (Anarcadium occidentale) were sampled at 0-20 cm depth for laboratory analysis of particle size, pH, C, N, P, EC and extractable micronutrients. The bulk densities at 0-5 cm, 5-10 cm and 10-15 cm depths were determined. Soil properties were analysed using descriptive statistics. The soil texture was sandy loam with soil pH ranging slightly acid to moderately acid (6.4 to 6.09). Irrespective of the local government areas, land use and OC (1.15 cmol kg^{-1}), N (0.08 g kg^{-1}), Na (0.74 cmol kg^{-1}) and P (4.91 mg kg^{-1}) were low. While Cu (7.68 mg kg^{-1}), Fe (112.00 mg kg^{-1}), Mn (154.5 mg kg^{-1}), Ca (4.09 cmol kg^{-1}) and K (0.233 cmol kg^{-1}) were medium and Mg (1.35 cmol kg^{-1}) were high. Total soil carbon (4011 kg C/ha) was very high. The bulk density ranged from 1.74 to 2.27 which were very high. In conclusion, most of the plantations were low in fertility, low carbon stocks which is assumed to be due to losses arising from continuous tillage practices and continuous cropping. The carbon storage status of land uses in the study area was low. Management practices like residue retention, use of organic fertilizer, green manuring, early harvesting and composting are recommended.

INTRODUCTION

Over the years, research efforts have indicated that crop production involves a complex interaction between the environment, soil parameters and nutrient dynamics (Ukpong and Moses, 2001). The failure to understand these complex interactions had resulted in lack of good quality and yield. The soil nutrient factor has therefore been found to be very important in the production of cashew in Nigeria (Ipinmoroti et al., 2011; Ipinmoroti and Akanbi, 2012). The evaluation of the soil physical suitability and constant monitoring of soil nutrient status have been advocated to ensure appropriate farm management for profitable arable and tree crop production in Nigeria (Ayoola and Agboola, 2002). In Nigeria and elsewhere in the tropics, extensive studies has been carried out on many tree crops including cocoa, coffee and cashew (Ipinmoroti and Ogeh, 2014), citrus (Pestana *et al.*, 2011), cocoa (Ololade *et al.*, 2010; Ibiremo *et al.*, 2010), cashew (Ramasamy *et al.*, 2013). Soil fertility levels vary, depending on the type and quality of minerals contained in their parent materials. The mineral nutrients in these parent materials are made available over decades, centuries, or longer through the process of weathering (Areola, 1982).

The soil nutrient factor has been found to be very important in the production of cashew in Nigeria (Ipinmoroti *et al*., 2011; Ipinmoroti and Akanbi, 2012).

For soil fertility to be sustained, extracted soil nutrients must equal replenished soil nutrients but in large areas of Africa, more soil nutrients are extracted than replenished (Ndala and Mabuza, 2006); thus, soil fertility and its management play an important role in farm productivity.

The need for improved crop productivity is more now than ever because of the increasing rate of population growth at about 3% in Nigeria (CIA, 2012) and the consequent pressures from competing demands for land over time have resulted in cultivable land being drawn from its traditional agricultural uses. Maintenance of soil fertility status is an important component of agricultural sustainability by most farmers, environmentalists and government policymakers (Sherwood and Uphoff 2000). Yakubu 2010, reported that soil fertility increases productivity, enables efficient use of nutrients, pesticides, water and lessening of greenhouse gas emissions. The characteristics of the soil affect many processes in the soil that qualify them for agricultural and other purposes. Therefore, assessing soil fertility involves measuring soil properties and using the measured values to detect changes in soil as a result of land use or management practices (Campos *et al*., 2007). Soil fertility is an important and essential components of a sustainable agricultural system in the tropical climates. The fertility status of a soil is a subject of soil characteristics especially physical and chemical property of the soil (Badalikova and Hruby, 2016).

The tropics are faced with the problem of declining per capital production, progressive deterioration of the environment and high spatial variability in the physical, chemical and morphological characteristics of soils which imply that different soils respond differently to land use types and management options. Also, continuous cultivation and indiscriminate deforestation through the use of fuel wood as source of alternative energy are attributed to the main source of declining per capital productivity of soils and fertility status especially in the rain forest zone (Chude *et al*., 2011, Osuji *et al*., 2011, Hassan *et al*., 2016). Land use affect soil fertility and productivity which manifest as change in soil properties such as nutrient content (N, P, K, Ca, Mg, S), pH, organic matter, CEC structure (Owoade *et al.,* 2020a, Owoade *et al*., 2020b). For instance Aluko and Fagbenro (2000) observed increase pH and organic matter for soil under teak (*Gmelina arborea*) than those under *Pins canaborea*, *Treculia Africana*, agroforestry and fallow land. He also observed increased phosphorus in fallow compared to other land uses. Successful agriculture requires the sustainable use of soil resource because soils can easily lose their quality and quantity within a short period of time for many reasons. Therefore, understanding of how soils respond to changes in management practice over time is essential in effective land management and hence ensuring soil quality. However, this can only be achieved when a good relationship has been established between soil fertility status and land use practices which may alter soil properties differently (Oyedele *et al.,* 2014).

Recent progressive increase in temperature results from global warming caused by rapid increase of the greenhouse gases concentration in the atmosphere since the industrial era (Daouda *et al*., 2017). In early May 2013, the atmospheric concentration of carbon dioxide (CO_2) reached 400ppm (Ralph, 2013). In terms of carbon emissions, the African continent accounts for 17% of global emissions from changes in land use patterns and management patterns (Bello *et al*, 2017). Changes in land use patterns contribute to 48% to Africa's total carbon emissions. This level has probably not been achieved in the last 20 million years and continues to increase at a rate of about 2 ppm per year. In general, tropical ecosystems are considered as sources rather than sinks of carbon dioxide since the savanna is grown and wood is harvested for energy and coal production (Tinlot, 2010). In the soil ecosystem, soil organic carbon influences soil physical and chemical processes, and serves as a source of plant nutrients. The balance between carbon gains and losses determines how much organic carbon can be stored in the soil. The balance between carbon gains and losses determines how much organic carbon can be stored in the soil. The processes of SOC storage or losses are influenced by biotic factors like biomass production and microbial abundance, mean annual precipitation and temperature, soil characteristics including texture and lithology and anthropogenic activities like land use and management (Olson, 2013). Predicting the effects of climate change will be made easier with a clear description of the distribution and changes of SOC as well as its controlling factors (Albaladejo *et al*., 2013).

MATERIALS AND METHODS

Description of Experimental Site

The study was carried out in three local government areas; Ogbomoso North Local Government Area, Orire Local Government Area and Surulere Local Government Area of Oyo State, Nigeria.

Field Study

Three different farms each in the three local government areas were studies, namely;

- Ogbomoso local government area: LAUTECH farm, katangua farm, Amamaa farm.
- Orire local government area: Olooru farm, Obamo farm, Fedegbo farm.
- Surulere local government area: Oloose farm, Iregba farm, Iresa adu farm.

Field study was carried out at the three different farms in each local government area, wherein three *Anacardium occidentale* trees were studied in each farm out of the three in each local government.

Soil Sampling and Laboratory Analysis

Soil samples were collected in triplicate with the aid of a soil auger. In each village, three farms planted each with *Anacardium occidentale* were sampled. Soils were collected from the farmland randomly at the depth of 0-20cm with the use of soil auger for physical and chemical analysis in the laboratory. The samples were bulked to form a composite and air dried, crushed and sieved through 2 and 0.5mm meshes for the determination of pH, particle size, C, N, P, cation exchange capacity (CEC), exchangeable cations (K, Mg, Ca, Na) and extractable micronutrients (Mn, Fe, Cu, Zn). The bulk density of each land use was taken 0-5cm and 10-15cm with core samplers. Laboratory analyses were carried out at the International Institute of Tropical Agriculture (IITA), Ibadan. Particle size analysis was carried out with the aid of hydrometer using sodium hexametaphophate as the dispersant (AOAC, 1990). Soil pH was determined in 1:1 soil water ratio (Black, 1965). Total nitrogen (N) was extracted by the macro-Kjeldahl digestion method (Bremner and Mulvaney, 1982) followed by colorimeter determination using Technicon Auto-analyser. Mehlich 3 (a multipurpose extractant) was used to extract available phosphorus, exchangeable cations (K, Mg, Ca and Na) and extractable micronutrients (Mn, Fe, Cu and Zn) (Mehlich, 1984). Phosphorus was determined colourimetrically using Technicon Auto- analyser, while the concentration of (calcium, magnesium, Copper, Zinc, Iron and Manganese) in the extract was determined by Atomic Absorption Spectrophometer. Sodium (Na) and Potassium (K) was determined using Flame emission photometer. Exchangeable acidity was determined by KCl extraction. CEC was determined by summation of Exchangeable bases (K, Mg, Ca and Na) and Exchangeable acidity. Organic carbon was determined by chronic acid digestion method (Heanes, 1984).

Determination of Bulk Density

The soil bulk density was evaluated using core method (Cresswell and Hamilton, 2002) as follows:

$$BD\ (g/cm^3) = \frac{\text{dry weight of oven soil (g)}}{\text{Volume of core } (cm^3)}$$

Where BD = bulk density (g/cm^3), volume of core = $\pi r^2 h$

Where π = 3.142, h = height of the cylinder, r = internal radius of the cylinder.

Determination of Carbon stock

Soil carbon stock (C-stock, kg/ha) at the 20cm depth was calculated from the total carbon content and bulk density (Ledo *et al.,* 2019) as follows:

C- Stock (kg/ha) = SOC x BD x A x D

Where SOC-soil organic carbon

BD-Bulk density (Mgm^{-3})

A-Area (1 ha = 10,000 m^2)

D-Soil depth (0.2 m)

Statistical Analysis: Data collected was analysed using analysis of variance (ANOVA) and significant means were compared using LSD at 5% probability level.

RESULT

The Mean Physiograpic Characteristics of *Cashew* in the Study Area.

The mean physiographic characteristics of cashew in the study area are presented in Table 1. The diameter breadth height (DBH) of the sampled trees ranged between 81.6 and 125cm. The height of most of the trees sampled ranged between 6 and 11.3m. The elevation of the area where data was collected ranged between 320 and 456.6m.

The Physical Properties of Soil under Locust Bean in Ogbomoso Agricultural Zone.

The physical properties of the soil under locust bean in the sampled area are presented in Table 2. Irrespective of local government, the soil under *cashew* trees was sandy loam. The bulk density was high for all the local government sampled. It ranges between 1.74 and 2.27g/cm^3.

The Chemical Properties of Soil Under cashew in Ogbomoso Agricultural Zone.

The chemical properties of soils in Ogbomoso agricultural zone (Table 3). The three local government area had significant effects on the soil pH while the villages did not significantly influence the pH content. The highest soil pH (6.44) which indicates a slightly acidic status was obtained from Oloose village in Surulere local government which was significantly higher than

LGA: Local government area.

DISCUSSION

In all the different land use types, sandy loam was the dominant textural type. The textural class was sandy loam in all the various land use types. The high percentage of sand could be attributed to the geology of the area. Soil texture is an important physical property of soils that is not easily changed by humans as a result of changes in land use (Brady & Weil 2017). High sand fractions could also be due to the parent material (coastal sand) considering the fact that the texture of a soil is highly influenced by the parent material and topography overtime (Oguike and Mbagwu, 2009). Similar report has been made by Udom and Ogunwole (2015) and Nwite and Alu (2017) that the dominance of sand fraction was recorded under different land uses in Nigeria.

The bulk density for lautech farm was high and it is very high in other farms in the study area and this due to the use of heavy farm equipments on the farm e.g. tractors, ploughs, and subsequent trips across the field by farm equipment, rainfall events, animals, and other disturbance activities will also compact soil. To prevent high bulk density in the soil some measures like minimizing soil disturbance and avoid operating equipment when soils are wet; using designated roads or rows for equipment; reducing the number of trips across a field; and practices that increase organic matter such as continuous no-till, cover crops, solid manure or compost application, diverse rotations with high residue crops and perennial legumes or grass used in rotation (USDA NRCS, 2019).

The levels of organic carbon in soils under cashew in the study area were low for some villages (Obamo, Iresa, Iregba, Oloose, Olooru, Fedegbo and Amama) and at medium level for lautech farm in the study area. Anderson-Teixeira *et al*. (2009) reported that conversion of uncultivated land for agricultural purpose results to significant soil organic carbon loss. This finding is supported by Anikwe (2015) who made similar observations and corroborated by Lal (2008) that trees trapped carbon dioxide from the atmosphere and sequestered it in plants' part and finally as soil carbon. According to Nair *et al*., 2010 and Nair, 2011 opined that factors that can influence the total amount of carbon sequestered include previous land use, tree species and density (broadleaves are higher sequesters compared to coniferous and deciduous trees), the type of agroforestry system (nature of components), age of perennials like trees (mature stands of trees have the capacity to storage more carbon compared to young stands), ecological region.

The villages have no significant on the phosphorus. In general, the soils were deficient in available phosphorus and phosphorus deficiency is likely to be an important factor limiting crop yield as the levels of the nutrient are well below 10mg/kg. The low phosphorous status of soils can be adduced to the practice of burning prior to cultivation, frequent cultivation and the slow rate of organic matter accretion in savannah fallow soil. Yang and Post (2011) reported that in tropical soils (e.g. oxisols) as the iron and aluminium content dominate soil mineralogy, leading to low phosphorus availability despite high total phosphorus content. According to Osman (2013) the cause for low available phosphorus might be resulted from high exchangeable acidity where phosphorus is combined with Al, Fe, and Mn (as their presence is predicted at the pH values of the soils of the study area) and becomes fixed.

In contrast to the level of phosphorus, the level of potassium in the soil under cashew was medium. The complete removal of crop residue, intensive cropping, extensive use of fertilizers (diammonium phosphate and urea) which include no potassium and non-use of mineral K fertilizer in soils of the study area might have led to the prevalence of K depletion (Hailu *et al*., 2015; Laekermariam *et al*., 2016; Wassie, 2019). The lower available K in the crop land could also be due to soil degradation and losses by leaching (Moges *et al*., 2013). There were however a significant build-up of exchangeable calcium and a decrease in the mean level of effective cation exchangeable capacity (ECEC) in the soil under cashew in the study area.

Phosphorous are low in all farms in the study area and the deficiency of this nutrients may affect the growth of plant and cause reduction in yield of crop. Low N content can occur because of leaching and volatilization owning to its mobile nature (Igwe and Akamigbo, 2001). The low nitrogen content recorded might also be as a result of absence of crop rotation with leguminous crops. According to Okpara and Igwe (2014) reported that legume-cereal rotations gave higher soil nitrogen than continuous maize whether there was addition of residues or not. Smil (2000) reported that when N and P are in excess in soils, they may be misplaced through leaching and erosion (for example, globally, an estimated 15 million tons of P are lost annually from crop fields due to erosion, and an estimated of 8 million tons of P are lost in runoff from arable land annually) (Cordell *et al*., 2009).

Magnesium was high in all the farms in the study area. Chlorophyll molecules in plant tissues have Mg as their main component. As a result, poor and stunted growth comes from a Mg deficiency due to a lack of chlorophyll. The enzymes systems are also helped by Mg. Mg also helps to activate specific enzyme systems. According to Grzebisz (2011), mobilization and leaching leads to lack of magnesium and calcium. Ayoubi *et al*. (2011) noted that several researchers have proven that deforestation and cultivation of virgin soils often leads to depletion of macronutrients and reducing soil quality. Banafshe *et al*. (2011) obtained lowest Mg in cultivated land which can be due to the high intensity of cultivation, abundant crop harvest with very little use of inputs and also leaching from forest or cultivated farm land.

CONCLUSIONS AND RECOMMENDATION

The pH of the soil is slightly acidic, which resulted in the low soil chemical properties N, P, OC and Na virtually in all the study area while all the micronutrients are higher for all the farms in all the local government area and very in other villages in the study area. The bulk density for the soil in LAUTECH cashew farm is high and this may be due to the use of heavy machines on the soil e.g. tractor, plough and continuous tillage practices which may expose the soil.

It is recommended in the study area that organic carbon or manure should be applied to the soil for improved crop yield and productivity and also practices that increase organic matter such as continuous row till, application of compost and solid manure to help reduce high bulk density in the soil and help increase the level of nutrient in the study area.

ABSTRACT

The variability of extreme climatic variables such as temperature, precipitation and soil texture has been significant in agricultural produce. These effects pose a major threat to agricultural development viz-a-viz cocoa production in the Idanre community. Cocoa production in the last decade has been marked by fluctuations and irregularities of these variables. This study's objective examine the variation in the trends of sunshine, temperature, rainfall and humidity on cocoa production in the community. Primary data were obtained from 10 selected wards from the 3 communities of Atosin, Alade and Odode that constitute the study area through a purposive sampling technique. In each of the selected streets and communities, the 2nd, middle and 2nd to last households were administered with questionnaires. A total of 90 copies of questionnaires were administered in 112 pollen unit stations and 82,449 numbers of registered voters were used for this study. The multiple regression analysis was applied. The results revealed that sunshine and temperature have only contributed significantly to cocoa production and that climate change has a huge and substantial effect on cocoa production in the Idanre community, Ondo State. The study recommends that more awareness of climate change should be created among cocoa farmers through public-private partnerships on the effects, coping and adaptation strategies of climate change.

***Keywords**: Extreme Climatic Variability, Irregularities, Cocoa Production, Idanre Community*

INTRODUCTION

The variables of climatic factors vary from one ecological zone to another. These variations could be attributed to frequency changes in weather and climatic conditions, environmental pollution and human interactions and intervention with the earth's resources. There is a connection between and among the indices of geography, climatic factors, environmental variability on crop production and food security (Agbebaku, 2021; Agbebaku and Agbebaku, 2023). Proceeds from agriculture activities especially cocoa production have been the second largest foreign exchange earner after crude oil in Nigeria. Given this importance, one would expect it to be produced on a large scale and its production should be on the increase to boost the nation's foreign exchange earnings. But despite the nation's commitment to increase cocoa production, it is still being faced with problems ranging from over-reliance on the oil sector, extreme climatic variability, neglect and inaccessibility of farm inputs for resuscitation of the product (NBS, 2012). Before the discovery of oil in Nigeria in the early 50s, the country's main domestic product was agriculture, the sector provided the country with employment and foreign exchange earnings but shortly after the oil boom in 1970, the contribution of Agriculture to GDP reduced to 22% in 2012 (NBS, 2012; Agbebaku and Agbebaku, 2023). Thus, the sector employs over 60% of the entire population in recent times where white-collar jobs are not forthcoming. Ethan (2015), opined that that in recent times, there has been a long-term temperature increase in most parts of Southern Nigeria on crop production.

These extreme climatic variabilities are plagued with diverse ecological problems in crop production in general and cocoa production in particular in the Idanre Community. Climate change is a threat to rural farmers especially those living in the tropics and subtropics. Among the most limiting factors to cocoa production is climate change. This is because every stage of cocoa production requires adequate weather conditions (Orimogunje, Ogundeji, Ademola, Balogun, Awodumila, Olorunmota & Oyeledun, 2020). Consequently, cocoa is highly susceptible to drought and pests' attacks but its cultivation is related to rainfall distribution (Koissy and N'Zué, 2020). Thus, several factors have interrelated impacts on the growth of cocoa plants. These factors range from the combination of the extreme conditions of; weather elements of rainfall, temperature, sunlight and humidity to others such as soil nutrient status, pests and diseases, and farmers' planting practices. The cocoa plant is known to produce well with minimal but sustained water availability throughout the year Furthermore, black pod diseases account for quite a lot of cocoa production losses by attacking the ripened or very young pods (Agbebaku, 2016; Orimogunje, et al., 2020; Okeniyi, Okeniyi & Mustopha, 2021).

The diseases are closely related to the pattern of rainfall distribution. It is more prevalent in damp situations with utmost pod infection in years when the short dry period from July to August is a very wet season. Nigeria Meteorological Agency (NIMET, 2011), states that some places in the South-West, Nigeria including Ondo state recorded rainfall values that were 200 -300 percent higher than normal. To this end, the researcher will employ variables of rainfall, temperature, humidity, and sunshine as proxies for climate change and cocoa production in the Ondo State context (Orimogunje, et al., 2020; Okeniyi, Okeniyi & Mustopha, 2021; Agbebaku and Agbebaku, 2023). The choice of the effects of extreme climatic variability on cocoa production in Ondo State, Nigeria, was predetermined by a combination of factors such as; Ondo State being rated as the largest cocoa-producing state in Nigeria, records of the fluctuations in some extreme variability of environmental and climatic factors especially rainfall, temperature and sunshine hours. The study aims to examine the variation in the trends of sunshine, temperature, rainfall, and humidity on cocoa production in Ondo state, Nigeria. The study objective is to examine the trends of sunshine, temperature, rainfall and humidity on cocoa production in the Idanre community of Ondo state.

Conceptual Clarifications

Cocoa Production

Cocoa was introduced into Nigeria in 1874 and the plant has since gained prominence rapidly in the country such that in the early seventies, cocoa production has spread to all the agroecological zones in Nigeria. Presently, 14 of the 36 states produce cocoa in the country; these states include, Ondo, Cross River, Osun, Ekiti, Ogun, Oyo, Edo, Delta, Kwara, Kogi, Abia, Taraba, Adamawa and Akwa Ibom (Oluyole & Sanusi, 2009; Adedokun, 2023). Cocoa has contributed to the economy of the country over the years and gained popularity because of the benefits from earnings and contribution to Gross Domestic Product (GDP) as the highest foreign exchange earner among all agricultural commodities (Oyekale, Bolaji & Olowa, 2009). However, the modest growth in the cocoa subsector has been traced among other things to include favorable weather conditions. Cocoa is highly sensitive to changes in climate, particularly to temperature due to its effects on evapotranspiration (Anim-Kwapong & Frimpong, 2005) and is known to thrive well with minimal but sustained water availability throughout the year (Obatolu, Fashina & Olaiya, 2003). Meanwhile, yearly variation in the yield of cocoa is affected more by rainfall than any other climatic factors. Cocoa prefers calm conditions and persistent moderate wind can cause severe damage to yield. Thus, being a selective plant, cocoa reacts badly to any incidence of extreme weather (Orimogunje, et al., 2020).

The International Cocoa Organization (2005), described extreme weather to include weather phenomena that are at the extreme of the historical distribution and observed that temperature and rainfall are important factors that impact optimum yield. This occurs when changes in weather elements alter the stages and rate of development of cocoa, cocoa pests, and pathogens, modify host resistance and result in changes in the physiology of host pathogens and pest interaction, causing a shift in the geographical distribution of host. This ultimately results in low cocoa yield and crop losses and a resultant effect on socio-economic variables such as farm income, livelihood and farm-level decision-making. However, basic skills in cocoa production, coupled with an optimum motivation, are sensitive requirements for best practices and consequently high-quality yield of cocoa (Ajewole & Iyanda, 2010). This is worrisome because agriculture (especially cocoa production) plays a significant role in supporting the livelihoods of individuals and the economic growth of many African countries (Okeniyi, Okeniyi & Mustopha, 2021; Agbebaku and Agbebaku, 2023). High dependence on agriculture and the predicted high negative impact of climate change on the productivity of agriculture draws a bleak picture of the rural and national economies of most West African states.

Climate Change on Environmental Variability

Climate change as a concept is used to explain changes in the earth's climatic system. It is concerned mainly with a change due to an increase in the average atmospheric temperature and ocean rise. The incessant features of desert encroachment, glacier melting, wind and wave patterns, floods, environmental imbalance and challenges, tsunamis, drought, epidermis-outbreak and ocean surges are clear indicators that the ecosystem is affected by climate changes (Agbebaku, 2021). Climate change is a function of environmental challenges and imbalance in the ecosystem, it is attributed to prolonged indices of environmental imbalance and environmental challenges. The variability of these indices results in climate change. The causes of climate change all over the globe are attributed to three main factors. The factors are (a)frequency changes in climatic variables, (b)environmental pollution, and (c)human interactions and relationships with the ecosystem. For instance, the frequency changes in climatic variables such as rainfall, temperature, wind and humidity) are major causes of climate change in regions of the world (IPCC, 2013; Afolayan, Agbebaku & Arhyel, 2022). Environmental pollution is a function of the amount of toxic waste and pollutants in the atmosphere. The amount and nature of greenhouse gases in space determine the environmental imbalance and climate change of a place. An increase or reduction of these gases in the atmosphere has adverse effects on the environmental challenges of a place. Greenhouse gases (GHGs), come from a variety of sources e.g. (machines, automobiles, bush burning, waste, fertilizer, insecticide, ashes, lava and stem). The manufacturing sectors and other related fields (fossil coal, industrial waste, oil and natural gas) also constitute mainly environmental pollution. Furthermore, the use of fossil fuels to meet the world's needs is another contributor to the increase in greenhouse gases e.g. (carbon dioxide (Co^2), chlorofluorocarbon and methane (Cunningham and Cunningham, 2015; Agbebaku, 2016 Agbebaku, 2021; Afolayan, Agbebaku & Arhyel, 2022).

MATERIALS AND METHODS

This paper is purely an experimental survey and a combination of content analysis of articles from journal publications, documentaries and field surveys. The study utilizes evidence mainly from primary and secondary sources from field surveys. Primary information was sourced from on-the-spot surveys of cocoa production farms. In essence, 10 selected wards from the 3 communities of Atosin, Alade and Odode were used for the study through the purposive sampling technique. In each of the selected streets and communities, the 2nd, middle and 2nd to last households were administered with questionnaires. A total of 90 copies of questionnaires were administered in 112 pollen unit stations and 82,449 numbers of registered voters were used for this study. The multiple regression and analysis of variance (ANOVA) were applied. Secondary data were sourced from documentary materials and established sources such as; existing literature, academic journals, conference papers, theses, internet materials and archival sources. Descriptive and purposive sampling techniques were used for this study.

RESULTS AND DISCUSSION

The results of the study were summarized and presented in Tables 1 to 4 showing the multiple regression of sunshine, temperature, rainfall, and humidity on cocoa production in the study area.

Table 1: Model Summary of Regression Analysis

Model	R	R Square	Adjusted R Square	Std. Error of the Estimate
1	.716[a]	.647	.615	.373

a. Predictors: (Constant), Sunshine, Temperature, Rainfall, Humidity

Source: This Study, 2023

The result from Table 1 indicated that the model had a correlation value of 0.716, which manifests a good linear relationship between the dependent and independent variables. The Table further showed that the goodness of fit (R^2) is 0.647 which depicted that 64% of the changes in the dependent variable (cocoa production) are accounted for by the independent variables (Sunshine, Temperature, Rainfall, Humidity). More so, the adjusted R square of 61.5% specifically indicated that the explanatory variables of Sunshine, Temperature, Rainfall, and Humidity account an approximate of about 62% of changes in cocoa production while the remaining 38% accounted for scholastic error term, that is, variables outside the regression model which also influence cocoa production in Ondo State.

Table 2: Analysis of Variance (ANOVA)

Model		Sum of Squares	Df	Mean Square	F	Sig.
1	Regression	10.314	4	6.105	15.751	.003[b]
	Residual	16.406	45	.139		
	Total	26.720	49			

a. Dependent Variable: Cocoa production

b. Predictors: (Constant), Sunshine, Temperature, Rainfall, Humidity

Source: This Study, 2023.

The findings from the ANOVA analysis presented in Table 2 help in indicating the weakness or the strength of the model. According to Belle (2008), an insignificant F-test value indicates a weak regression model. From the findings obtained in Table 2, the F-test value is 26.720 which is greater than F- tabulated of 3.64 with a significance value of 0.000 at 0.05 level of significance. Since the F-test value of 26.720 is far greater than the 3.64 F-calculated value and the P-value obtained 0.000 was <0.05, it implies that the overall model is significant. The F-test is significant hence the conclusion that the regression model was good. This showed that the model does not suffer from specification bias.

Table 3: Regression Coefficients

Model		Unstandardized Coefficients		Standardized Coefficients	t	Sig.
		B	Std. Error	Beta		
1	(Constant)	1.524	.320		4.766	.000
	Sunshine	.088	.110	.118	3.798	.009
	Temperature	.141	.142	.192	3.990	.004
	Rainfall	-.232	.161	-.278	-1.447	.155
	Humidity	-.060	.113	-.081	-.530	.599

a. Dependent Variable: Cocoa production

Source: Field Survey, 2023

From the Table above, the following regression equation was established

$COCO= 1.524 + 0.088_{SUN} + 0.141_{TEM} - 0.232_{RAIN} - 0.060_{HUM}$

The coefficient of sunshine is 0.088 which is significant and positively related to cocoa production in Ondo State. This implies that a 1% change in the sunshine will positively and significantly increase cocoa production in Ondo State Nigeria by 08.8%. Therefore, it can be concluded that sunshine positively and significantly influences cocoa production in Ondo State, Nigeria. Also, the coefficient of temperature plays an increasing role in the production of cocoa production in Ondo State to the tune of 0.141. By implication, this suggests that temperature has a positive and significant effect on cocoa production at a 5% level of significance. If the temperature continues to increase, it will increase photosynthesis, thereby increasing the output of cocoa production in the Ondo State. Furthermore, the coefficient of rainfall is estimated to be -0.232 which indicates a negative and insignificant effect on cocoa production. Therefore, a percentage increase in rainfall will produce about a 23% change decrease in cocoa production. The hypothesis that rainfall positively and significantly influences cocoa production is rejected. Lastly, the coefficient of humidity is 0.060 which showed a negative and insignificant effect on cocoa production in Ondo State Nigeria. The result therefore implies that a percentage change in humidity will bring about a decrease in cocoa production by 6%. Hence, humidity has a negative and insignificant effect on cocoa production in Ondo State, Nigeria.

Table 4: Summary of Test of Hypotheses

Hypothesis	Independent variable	Dependent variable	$p < 0.05$	Decision
H_{01}	Sunshine	Cocoa production	.009	Reject H_0
H_{02}	Temperature	Cocoa production	.004	Reject H_0
H_{03}	Rainfall	Cocoa production	.155	Accept H_0
H_{04}	Humidity	Cocoa production	.599	Accept H_0

Source*:* This Study, 2023.

DISCUSSION

The research hypotheses were tested through a t-test of regression analysis which found that sunshine and temperature are among the variables that significantly affect cocoa production in Ondo State Nigeria. Ideally, increasing temperatures reduces cocoa yield. Temperatures are expected to keep rising over the 21st century due to climate change, the number of heat spells will increase and cold spells will decrease (Change, Intergovernmental Panel on Climate, 2013). Sofoluwe, Tijani, and Baruwa, (2011), claim that even slight temperature changes are likely to greatly affect yields and some types of cocoa plants are already at their temperature limit, causing a reduction in yields and potentially shunting growth. Nonetheless, temperature increases cocoa production as found in the analysis, yet, when temperature increases, it decreases rainfall, and raises humidity which can both stand as factors that threaten the impact of cocoa crop (Sofoluwe, Tijani, & Baruwa, 2011). As a result of these factors, cocoa production will likely be affected as climate change progresses. The finding of this study corroborates the finding of Koissy and N'Zué (2020), that temperature and sunshine significantly impact crop production in Nigeria. Thus, the results revealed that sunshine and temperature have only contributed significantly to cocoa production and that climate change has a huge and substantial effect on cocoa production in the Idanre community, Ondo State.

CONCLUSION AND RECOMMENDATIONS

Cocoa cultivation as one of the major cash crops in Ondo state and also a major agricultural produce that contributes significantly to employment generation and foreign exchange in the country has been observed with marked fluctuations which could be attributed to the change in climatic variables over the years. Given the above, the study however, concluded that the climate of Ondo state is not stable and this amongst other factors has brought about fluctuations in cocoa production in the study area. Thus, the study recommends that more awareness of climate change should be created among cocoa farmers through public-private partnerships on the effects, coping and adaptation strategies of climate change

ABSTRACT
Crops response to nutrients effect in terms of growth and yield; soybean is not an exception to the major nutrients. Hence, a pot experiment was conducted in Ogbomoso, Oyo State, Nigeria to determine the response of ten soybean varieties to NPK fertilizers. The treatments are: NPK application; (NAF-No fertilizer application), (P+K-Phosphorus and potassium), (P+N-Phosphorus and Nitrogen), (P; phosphorus alone) and (N+P+K application). It was a factorial experiment, laid in Completely Randomized Design with four replicates. Data collected are: plant height and number of leaves, flowers and pods, weights of; fresh and dry biomass, root and dry matter, and nutrient uptake. Data were subjected to Analysis of Variance and treatment means were separated using (DMRT $^{a}{}_{0.05}$). In conclusion, the interactions between the two factors were highly significant on the growth parameters and nutrient uptakes. The interactive effects on soybean variety TGm1057 under NFA produced the highest fresh shoot and root weights, while under (P+K) application, TGm1052 had the highest fresh root weight. Variety TGm1057 under NFA has the highest N uptake while variety TGm1052 under (P+K) application had the highest P uptake. But TGm1057 under (P+N) application had the highest N and K uptake. The highest soybean pod yield was obtained from variety TGm1052 under phosphorus and potassium (P+K) application while TGm1057 had the least yield under the same fertilizer application. In conclusion, it can be recommended that soybean variety TGm1057 be cultivated with little or no N fertilizer but with phosphorus and potassium fertilizer application for optimal pod yield.

INTRODUCTION

Soybean (*Glycine max* L. Merrill) is an important leguminous and oilseed crop that is widely grown because it is adaptable to different agro-ecological zones (Agarwal and Singh, 2015). Soybean is the world's leading source of protein and oil. It has the highest protein content of all food crops and is second only to groundnut in terms of oil content among grain leguminous crop (Ikeogu and Nwofia, 2013). Soybean is a plant that possesses the traits such as; high nutritional value, resistance to diseases and pests, and lower susceptibility to lodging compared to other legumes (Gawęda *et al*. 2016). It is one of the most important fodder plants which account for about 58% of total oilseed production worldwide and 69% of protein in the diet of livestock animals (Borawska *et al*. 2014). Soybean is high of polyunsaturated fatty acids, refers to as one of the most valuable oilseed plants (Agarwal, 2013; Medic *et al*. 2014). Due to its high nutritional value and beneficial effect on the soil, there is increasing interest in soybean cultivation (Jaskulska *et al*. 2017).

Soybean is among the major industrial and food crops grown almost in all agro-ecological zones in Nigeria. The crop is successfully grown in Nigeria with low agricultural input; this has made its cultivation to be expanded coupled with its nutritional and economic importance among other diverse local uses. The seeds contain about 20% oil on a dry matter basis and this is 85% unsaturated and cholesterol-free. The rapid growth of both the poultry and food processing industries in the past decade has also increased demand for soybean in Nigeria (Xiang, Yong, Yang, Wan, Gong, Cui & Lei , 2012).

However, its cultivation and production increased as farmers were aware of the potential of this crop for cash, food and for soil fertility improvement and Striga control (Omoigui *et al*., 2020). There are several soybean varieties; Notable promising soybean varieties for both southern and, northern guinea, savanna and sudan savanna zones are: TGX 1448-2E, TGX1951-3F, TGX 1904-6F, TGX 1987-62F and TGX 1987-10F. However, it is important to choose a variety suitable to particular agro ecological zone. Hence, variety selection should be done based on the time to maturity, yield potential, susceptibility to stem lodging, drought tolerance, and resistance to pests and diseases. The maturity period should be considered when choosing a variety, suited to your geographical zone. Although late maturing varieties have the potential to increase in yield, but the danger of late-season drought is eminent (Omoigui *et al*., 2020).

Despite the high yielding potentials of soybean across the production zones, there are number of reasons identified for declining productivity of the soybean viz., heavy or very low rainfall, pests and diseases attack, pests to diseases susceptibility, imbalanced use of fertilizers, soil fertility problems, low soil organic matter, water stress, poor management *(*Walikar *et al*., 2018*);* Lu and Tian, 2017). Moreover, the problem of soybean response to the major nutrients; nitrogen, phosphorus and potassium (NPK) is soil has received little or not much research focus in most soybean producing zones in Nigeria. According to Mourtzinis *et al*., (2018), soybean seed production requires larger amounts of N compared to cereal crops because of its chemical composition, however, soybean response to N fertilization has not always increased seed yield. Moreover, N fertilizer application reduces the biological N fixation (BNF) activity by inhibiting the process (Mourtzinis *et al*., (2018). Soybean plants assimilate a large amount of nitrogen (about 330 kg N ha^{-1} for a yield of 4 t ha-1) during vegetation period, and the amount of N adopted in a plant is highly correlated with the soybean seed yield (), as well as with the chemical composition of soybean grains (Gai *et al*., 2016; Popović *et al*., 2016).

On the other hand, Phosphorus is a vital element in crop production which performs important role for many characteristics of plant growth such as sugar and starch utilization, photosynthesis use, cell division and organization, nodule formation, root development, flower initiation and seed and fruit development (Gangasuresh *et al*., 2010; Sanginga *et al*., 2015). The role of Potassium (K) is essential as factor for optimal production of soybean crops (Redel, Escudey, Alvear & Borie, 2011). It is the most abundant cation in plants involved in many physiological processes which include activating over 80 enzymes, regulating cellular osmotic water potential, photosynthesis, protein metabolism, and helping plants adapt to environmental stresses (Walikar, Bhan, Giri, Dubey & Agrawal, 2018).

From the various established works about soybean response to NPK, there is need to be soybean varietal specific in their response in term of yields and other growth parameters. Hence, the aims of the work are: to assess the response of different soybean varieties to various inorganic fertilizers in Ogbomoso agro-ecology and to identify the soybean variety and the inorganic fertilizer that would have highest significant effect on soybean performance.

MATERIALS AND METHODS

Experimental site: A screen-house experiment was carried out at Faculty of Agriculture, Ladoke Akintola (LAUTECH) Teaching and Research Farm, Ogbomoso, Oyo State, located on longitude 4° 30'E and latitude 10° 5'N. The climate hot, humid, tropical, of southern guinea savannah of Nigeria with mean temperature of 27°C, annual rainfall of 1400mm and marked with wet and dry season.

Soil sampling and pre-planting soil analysis: Soil samples were collected at a depth 0 – 20 cm from the Teaching and Research Farm of University of Technology (LAUTECH). The soil collected was used to filled the pots (5 kg polythene bag size). Parts of the composite soil samples were air dried and processed for physical and chemical analyses.

Source of Soybean seeds and fertilizer: Ten varieties of soybean seeds were obtained from the genetic resources center, IITA, Ibadan. The varieties are; (TGm 1002 = V_1, TGm 1052 = V_2, TGm 1057 = V_3, TGm 1434 = V_4, TGm 1537 = V_5, TGm 1816 = V_6, TGm 1817 = V_7, TGm 264 = V8, TGm 4360 = V_9, TGm 623 = V_{10}).

The following were nutrients evaluated: Phosphorus (P), Nitrogen (N) and Potassium (K). Nitrogen was supplied using urea, while phosphorus and potassium were supplied using SSP and MOP respectively. Basal application of fertilizers were done at; 20kg nitrogen, 40kg P_2O_5 and 20kg K_2O, per hectare respectively, before planting.

Fertilizer application/treatments application: The fertilizers recommended rates for the experiment, are: Urea-0.11 g/ 5 kg pots, MOP-0.06 g/ 5kg pot and SSP-0.24 g/ 5 kg pots; the treatments are: NAF= No fertilizer application, P+K = Phosphorus and potassium application, P+N = Phosphorus and nitrogen application and P only = Phosphorus application alone and NPK application.

Experimental treatments, design and layout: The pots/ bags for the experiment were arranged in a Completely Randomized Design (CRD) with each treatment replicated four times, given a total number of two hundred (200) experimental units or pots.

Sowing and other agronomic practices: Four seeds were sown per pot at a depth of 2 cm and latter thinned to two per pot, manual irrigation were carried out except on raining days and weeding was regularly carried out. Cypermethrin was applied was applied to control pests.

Data Collection and analysis: The following data were collected biweekly after sowing: plant height (cm), numbers of leaf, number of pods, plant weight and root weight (g), Nutrient uptake (nitrogen, potassium and phosphorus (NPK) uptake.

All data collected were subjected to analysis of variance (ANOVA) and significant means were compared with Least Significance Difference at 5% probability level.

RESULTS AND DISCUSSION

Experimental soil used: The chemical and constituents and the particle sizes results of the experimental soil used reveal that the soil pH is slightly acidic (6.50) while the soil organic carbon and nitrogen are (0.55 and 0.05 g kg^{-1}) very low but the available phosphorus was (105.94 mg kg^{-1}) very high. The potassium and calcium of this soil are of low values; (0.17 and 3.39 cmol kg^{-1}) while Mg and Na are 0.40 and 0.08 cmol kg^{-1}, respectively. The micronutrients (iron, manganese, copper and zinc) values ranged from 6.79 – 273.87 cmol kg^{-1} of which Fe was very high. The exchangeable cations (K, Ca, Mg, Na) values ranged from 0.08 – 3.39 cmol kg^{-1} while the exchangeable acidity was infinitesimal. The values of sand, silt and clay particles showed that the soil textural class was loamy sand (Table 1).

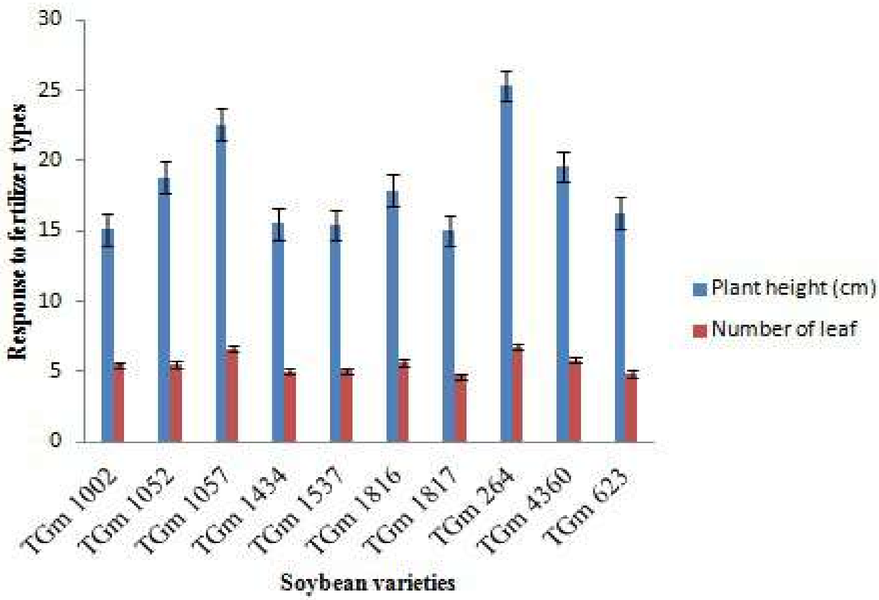
Table 1: The chemical composition and the particle sizes of the experimental soil used

Soil pH, Org. Carbon, TN and Available Phosphorus		**Exchangeable cations (cmol kg^{-1})**			**Micronutrients (mg kg^{-1})**	
pH (H_2O)	6.50	K	0.17		Fe	273.87
Organic carbon (g kg^{-1})	0.55	Ca	3.39		Mn	150.20
Total Nitrogen (g kg^{-1})	0.05	Mg	0.40		Cu	6.79
Av. Phosphorus (mg kg^{-1})	105.94	Na	0.08		Zn	198.80
		Exchangeable acidity		0.00 cmol kg^{-1}		
		Sand	**Silt**	**Clay**	**Textural class**	
Particle size distribution (g kg^{-1})		82	5.0	12.0	Loamy sand soil	

Soybean number of leaf: At 6 weeks after sowing (6WAS), there was varietal significant difference in the number of leaf per the fertilizers application, the mean numbers of leaf of the soybean plant ranged from 5 – 7 while under the various fertilizers application, the number of leaf ranged from 5 – 6. It was observed that soybean varieties under P application had 6 leaves (mean value of 5.93) the application of P and N had the lowest number of 5 leaves (mean value; 5.10), while variety 8 (V8 = TGm 264) had 7 leaves (mean value; 6.80) and the least number of leaf (4.70) was observed with variety 7 (V_7 = TGm

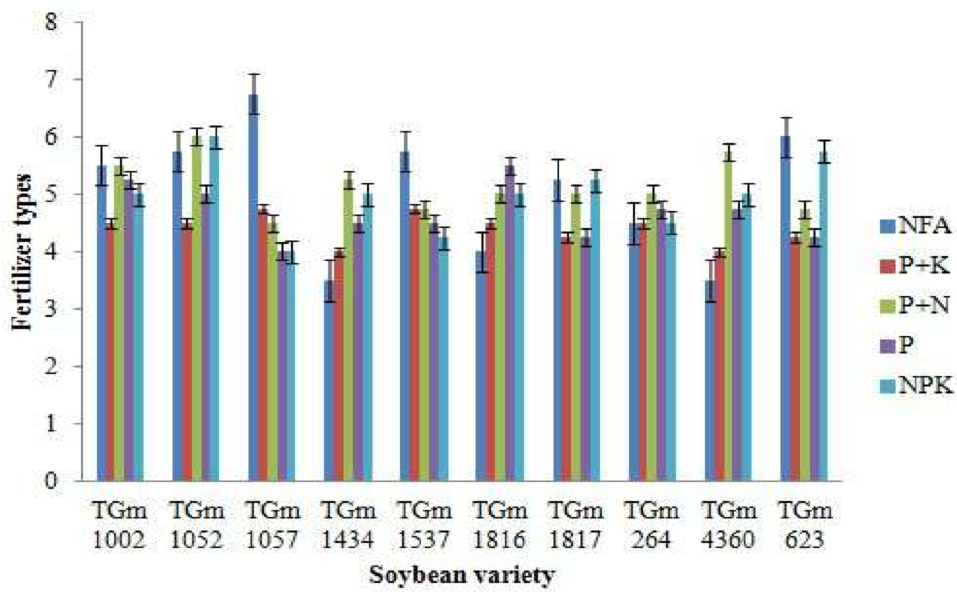
1817). However, there was no significant interaction effect between the fertilizer application and soybean variety on the number of leaves at 6 weeks after sowing (Figure 1).

Plant height: At 6 WAS, on average, all the soybean varieties the least (17.27 cm) and the highest (19.12 cm) plant heights under P+N and NFA fertilizer application, respectively, however, while on the variety basis of responding to fertilizer application the TGm 1817 had the least plant height (15.05cm) and the highest (25.35 cm) plant height was observed with variety TGm 264. There was significant varietal effect as well as significant interaction between the fertilizers and the variety (Figure 1).



Bars represent the $LSD_{0.005}$

Figure 1: Response of plant height and number of leaf different soybean variety to different fertilizer types at 6WAS



Bars represent the standard error (SE)

(NAF)= No fertilizer application, (P+K) = Phosphorus and potassium application, (P+N) = Phosphorus and nitrogen application and (P) = Phosphorus application alone (NPK) application

Figure 2: Number of pod of ten varieties of soybean as influenced by fertilizer types

Under the application of NFA soybean varieties TG_m1057 and 623 highest number of pods while TG_m1434 and 4360 has the least number of pods under the NFA application (Figure 2).

Yield parameters: Under the applications of all these fertilizer types, the fresh and dry root weights of the ten soybean varieties ranged from 0.73 – 1.76g (fresh) and 0.22 – 0.42g (dry), respectively. Similarly, variety TGm1002 had the lowest total fresh biomass (5.25g) while TGm264 had the highest total biomass. Meanwhile, this pattern was not followed other yield parameters that were observed under all the fertilizer types. However, the pod yield ranged from TGm 1002 (8.77g) - TGm264 (11.46g) as average pod yield under the different fertilizer application, Howbeit, there were significant effect of these fertilizers on the yield parameters both on each soybean variety so also the interaction of the fertilizer types on the variety (Table 2).

Table 2: The response of different varieties of soybean to different fertilizer types

Soybean variety	Soybean yield parameters weights (g/pot)					
	Fresh yield parameter weights		Dry yield parameter weights			
	Root	Total biomass	Root	Pod	Total biomass	Dry matter
TGm 1002	0.73	5.25	0.23	8.77	3.62	1.926

Interaction effects of variety and fertilizer:

The interaction effects of variety and fertilizer on mean performance of soybean; for root, pods and shoot of soybean (Table 3), showed that there were significant interactive effects between the variety and fertilizer application, and these effects are noticeable on the fresh shoot and root weights of variety 3 (TGm 1057) and under NAF (No fertilizer application) treatment, which makes it the best plant and treatment that aids root development. Also the interaction between the variety and treatment had significant effects on the dry shoot and dry root weights of variety 3 (TGm 1057) under P+N application (Table 3).

Table 3: Interaction effects of different variety and fertilizer types on growth and yield performance

DISCUSSION

The availability of nitrogen (N), phosphorus (P) and potassium (K) among other nutrients in soil are essential for the growth and yield of crops generally (Broch & Ranno, 2012). However, deficiency of phosphorus has been identified as the most limiting nutrient in soybean production as proved in this trial which corroborated Karikari *et al.,* (2015) findings. This may be attributed to the immobility of P in soils (Table 2). Nitrogen is less needed nutrient for soybean due to its ability to fix nitrogen, but most soils in the tropics are low in nitrogen (Table 2). However, nitrogen and phosphorus fertilizer application among other nutrients will have a residual effect on the successive crops grown on such soils (Xiang,Yong, Yang, Wan, Go, Lei, 2012).
Plant height was significantly affected by phosphorus and potassium fertilizer as noticed in the interaction with the soybean variety. TGm264 produced the tallest plant while TGm1816 produced the shortest plant

under these two nutrients application. At the end of the experiment, maximum plant height of 25cm was recorded (Figure 1). The pot experiment thus confirmed the results of the field experiment where increase levels of potassium resulted in taller plants as reported by Snyder (2000). These findings are similar to those of Qureshi *et al (*2010) who found a significant increase in plant height due to phosphorus fertilizer application, as also reported by Qureshi, Beg and Siddiq, (2003).

The highest soybean seed yield was obtained from variety TGm 1052 under phosphorus and potassium (P+K) application while TGm1057 had the lowest yield under the same fertilizer application. The result is in agreement with that of Pauline *et al*. (2010), and Aise *et al*. (2011) who reported a similar finding on soybean seed yield application of P+K fertilizer. According to IITA (2000) report, and Popovic *et al.* (2016), other factors such as rainfall distribution, among other factors, substantially modify the quantity and quality of soybean seed yield. The soybean seed yield reduction at the lowest and highest P- fertilizer application was been recorded because, the growth and development of soybean was influenced by little or excess of phosphorus as reported by Xiang *et al.,* (2012). More conclusive results on yield responses of soybean were obtained in experiment conducted by Qureshi, Beg and Siddiq, (2003), where the yield was increased.

Nutrients uptake pattern by these varieties of soybean revealed that phosphorus uptake was significantly affected by the use of different fertilizers source and soybean cultivars. The uptake of nutrients was significantly related to the total biomass produced by a cultivar, the increase in P uptake with the application of phosphorus over control (NFA) was significant. This showed that the application of P to soybean improved the efficiency of cultivars in accumulating more P, N and K (Mustafa, Darwesh & Luay, 2013).

From this trial, it can be deduced and recommended that this finding provides evidence that the application of P fertilizer positively influenced soybean growth and yield. And that soybean cultivar TGm1052 with highest performance under (P+K) fertilizers application is recommended for cultivation especially in soil with low nitrogen.

ABSTRACT
Carrot is gaining more popularity due to its nutritional, health and economic benefits. Recently, the production of carrot has been on the decrease as a result of low fertility status of the soil. Hence, pot experiment was conducted in 2022 cropping season at the College of Agriculture, Kabba to examine the impact of different fertilizer sources on growth and yield of carrot. The treatments included four fertilizer sources (0 t/ha (control), 10 t/ha of cow dung, 10 t/ha of poultry manure and 200 kg/ha of NPK (20:10:10)). The experiment was laid out in Completely Randomized Design (CRD) with five replicates. Analysis of variance result showed that fertilizer sources had positive impact on most of the traits assessed. Plants treated with poultry manure exhibited superior performance in terms of plant height, canopy diameter, root length and root diameter than others. It was evident that number of leaves was more in plants that received cow dung. Fresh shoot weight and total fresh weight were highest in plants fertilized with cow dung. Interestingly, plants grown with poultry manure produced the heaviest root weight. Heaviest dry shoot weight, total dry weight and highest shoot/root ratio was associated with plants grown with cow dung. Dry root weight and percent dry matter distribution to the root were obtained in plants treated with poultry manure. Percent dry matter distribution to the shoot was highest in the control. In conclusion, application of poultry manure that increased plant height, canopy diameter, root length, root diameter and root weight is recommended for carrot growers in the study area.
***Keywords**: Carrot, fertilizer sources, growth, yield*

INTRODUCTION

Carrot (*Daucus carota* L.), an herbaceous biennial plant belonging to the family Apiaceae (Kabir *et al.,* 2013). It is an important short duration root vegetable (Afrin *et al.,* 2019) and it is cultivated in many parts of the world (De Lannoy, 2001; Melese *et al.,* 2018). Carrot is becoming more popular especially among the urban people because of its high nutritive value and possible diversified use in making different palatable foods. Carrot is used as salad and as cooked vegetable in soups, stews, curries and also used for the preparation of pickles, jam and sweet dishes (Kabir *et al.,* 2000). Carrot contains appreciable amount of carotene, thiamin, riboflavin, iron, calcium, phosphorus and also serves as a source of carbohydrate, protein, fat, minerals, vitamin C and calories (Kabir *et al.,* 2000). Despite the enormous benefits of carrot, its yield per hectare had been greatly hampered by the low fertility status of the soil, faulty nutrient application and the type of fertilizer. The type and the way producers are applying fertilizer is one of the major problems in carrot production (Hailu *et al.,* 2008).

Soil nutrients could be supplied in organic or inorganic form (chemical fertilizers and lime) and in combinations (Aba *et al.,* 2020). In most cases, carrot growers use chemical fertilizers as the major supply of nutrients to attain higher growth and yield (Hochmuth *et al.,* 1999; Amjad *et al.,* 2005). Excessive amounts of inorganic fertilizers are being applied to vegetables in order to achieve a higher yield (Abou *et al.,* 2012). However, the use of inorganic fertilizers alone may cause problems for human health and the environment. Manure can serve as a substitute to synthetic fertilizers. Application of manure supplies the required nutrients; improves soil structure, water holding capacity, porosity, bulk density, moisture retention; increases microbial population; and maintains crop quality (Dauda *et al.,* 2008; Adekiya and Agbede, 2009; Adeleye *et al.,* 2010; Agbede *et al.,* 2013, 2014). Report by Abou *et al.* (2012) showed that vegetative growth and yield of different crops were increased with addition of organic manure. Khandaker *et al.* (2017) investigated six different fertilizers sources (no fertilizer, NPK fertilizer, poultry manure, rat manure, goat manure and rabbit manure) on the growth and yield of okra, according to the study, application of poultry manure significantly increased the growth and yield performances on okra compared to other types of organic fertilizers. There is limited information on the effect of different organic sources on growth and yield of carrot in the study area. Therefore, the study evaluated the influence of different organic sources on growth and yield of carrot.

MATERIALS AND METHODS

Experimental site: The experiment was conducted at the Horticulture section, College of Agriculture, Kabba (7.8231˚N, 6.0732˚E and 400 m above sea level). The area is located in the Southern Guinea Savanna Zone of Nigeria. The monoidal rainfall spans April to November with peak in June and dry season extends from December to March. The mean annual rainfall is 1570 mm per annum with an annual temperature range of 18-32˚C. The mean relative humidity is 60%.

Plant material: Carotte touchon variety was obtained from a seed company at Zaria and used for the experiment. A total of ten seeds were planted into polyethylene bags of size 48 x 38.5 cm filled with 8 kg soil in May 2022. The polyethylene bags were perforated to allow water to drain and to improve aeration. After emergence, the seedlings were thinned to three per pot. Watering was done as required. Weeding was done by hand-pulling the weeds from the pots as well as hoeing the weeds between the rows.

Treatments and Experimental Design: The treatments comprised of four fertilizer sources (0 t/ha (control), 10 t/ha of cow dung, 10 t/ha of poultry manure and 200 kg/ha of NPK (20:10:10)). The experiment was laid out in Completely Randomized Design (CRD) with five replicates.

Fertilizer application: The required quantity of cow dung, poultry manure and NPK fertilizer was applied in split doses.

Data Collection: Data were collected on plant height, number of leaves, canopy diameter, root length, root diameter, fresh shoot weight, fresh root length and total fresh weight. In addition, dry shoot weight, dry root length, total dry weight, shoot/root ratio, percent dry matter distribution to the shoot (%DMS) and percent dry matter distribution to the root (%DMR) were also taken. Oven dry weights of the shoot and root were taken from which dry matter content and distribution were estimated. The various plant parts were oven dried at a temperature of 80°C to a constant weight. All the data were taken at harvest. Harvesting was done in August, 2022.

Data Analysis: All the data collected were subjected to Analysis of Variance (ANOVA) following the procedure for experimental design in Completely Randomized Design (CRD) using GENSTAT (2013) statistical software package. Mean separation was done using Least Significant Difference (LSD) at 5% probability level.

RESULTS AND DISCUSSION

Physico-chemical properties of the potted soil, poultry manure and cow dung used in the study is shown in Table 1. The results indicated that the soil is characterized as sandy clay loam with low pH in water (5.10). The soil organic carbon, nitrogen and phosphorus were low at 1.33%, 0.09% and 7.11 ppm, respectively. The K^+, Ca^{2+} and Mg^{2+} were 0.10, 1.00 and 1.20 cmol kg^{-1}, respectively. The poultry manure and cow dung used shows high contents of nitrogen (1.35 and 1.21%), phosphorus (0.54 and 0.48%) and potassium (0.19 and 1.03%). The poultry manure and cow dung have the potential to enhance plant growth. Chukwuka and Omotayo (2009) reported that application of organic fertilizers significantly improves the soil chemical properties and nutrient uptake in plants which in turn enhanced plant growth.

Plant height, number of leaves, canopy diameter, root length and root diameter of Carrot were positively influenced by different fertilizer sources (Fig.1). It is pertinent to know that soil amendment using organic manures improved the growth and yield attributes of carrot than others. The maximum plant height, canopy diameter, root length and root diameter were attributed to plants treated with poultry manure. This was directly followed by cow dung. The least was obtained in plants that grew where no fertilizer was applied. The result obtained in this study was attributed to the sufficient amount of nutrients supplied by poultry manure which enhanced the growth and yield attributes of carrot. The superior performance of the poultry manure as reported herein is in agreement with the results obtained by Maxime Merlin *et al.* (2020) in carrot where chicken manure application enhanced root length and root diameter than other treatments. Ani and Baiyeri (2008) reported that poultry manure is the richest of the animal manures and is a valuable source of nutrients, organic matter, particularly nitrogen and potassium. Chukwuka and Omotayo (2009) reported that application of organic fertilizers significantly improves the soil chemical properties and nutrient uptake in plants which in turn enhanced plant growth. It was evident that number of leaves was highest in plants that received cow dung than others. The least was recorded in the control. The result obtained in this work contradicts the findings of Kiran *et al.* (2016) who reported increase in number of leaves of carrot in plants treated with NPK.

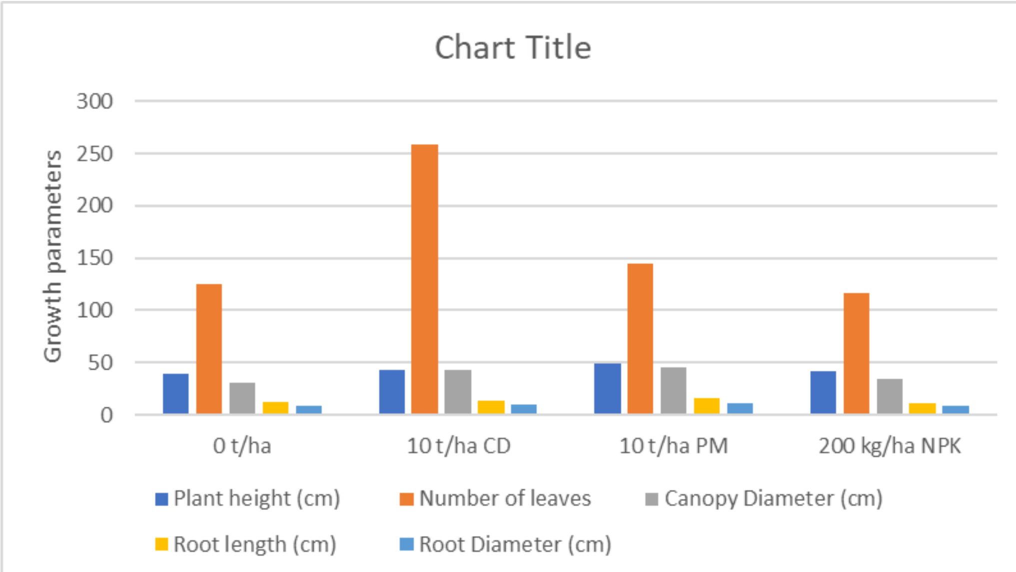

Figure 1: Plant height, number of leaves, canopy diameter, root length and root diameter of Carrot as influenced by different fertilizer sources. CD-Cow dung and PM-poultry manure.

Figure 2 presents the influence of fertilizer sources on fresh shoot weight, fresh root length and total fresh weight of carrot as affected by different fertilizer sources. Application of organic manures increased most of the traits assessed. Fresh shoot weight and total fresh weight were highest in plants fertilized with cow dung which was followed by plants treated with poultry manure. However, fresh shoot weight was lowest in plants that received NPK. The least total fresh weight was obtained in the control. It is interesting to note that application of poultry manure which increased plant height, canopy diameter, root length and root diameter also produced the heaviest root weight. The result obtained here could be linked to adequate nutrients supplied to the plants which increased yield attributes of carrot. The result is in accordance with the findings of Maxime Merlin *et al.* (2020) who reported that application of chicken manure significantly increased yield parameters of carrot than others. The inability of NPK to increase fresh shoot weight could be as a result of acidification. Qaswar *et al.* (2020) reported that NPK application decreased soil pH and increased soil acidification, whereas organic matter addition buffered acidification. For certain reasons, organic manure is preferred to inorganic fertilizers. Apart from adding nutrients to the soil (Ndukwe *et al.,* 2009), it also improves soil structural properties (Thompson and Troeh, 1978) and acts as a liming material by reducing soil acidity (Olatunji *et al.,* 2012).

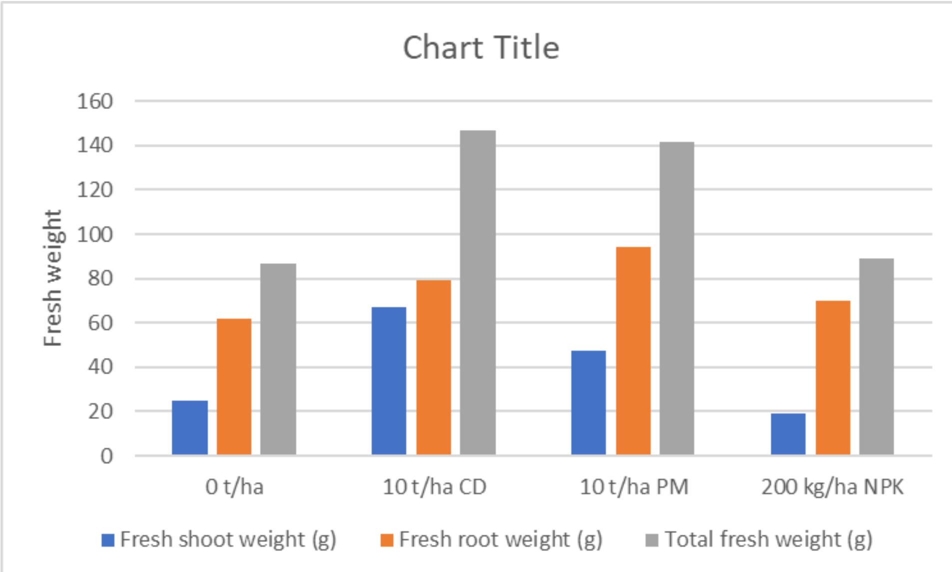

Figure 2: Fresh shoot weight, fresh root length and total fresh weight of carrot as influenced by different fertilizer sources. Cow dung and PM-poultry manure.

As shown in Fig. 3, different fertilizer sources positively impacted dry shoot weight, dry root length, total dry weight, s/r ratio, %DMS, %DMR of carrot. Heaviest dry shoot weight, total dry weight and highest shoot/root ratio was associated with plants grown with cow dung. The least was recorded in the control. Dry root weight and percent dry matter distribution to the root were obtained in plants treated with poultry manure. The lowest was obtained in the control where no fertilizer was applied. Dry matter allocation to the root which was associated with the application of poultry manure seem impressive. Root development as enhanced by poultry manure could be a strategy for survival in the harsh savanna environment. Percent dry matter distribution to the shoot was highest in the control but lowest in plants treated with poultry manure.

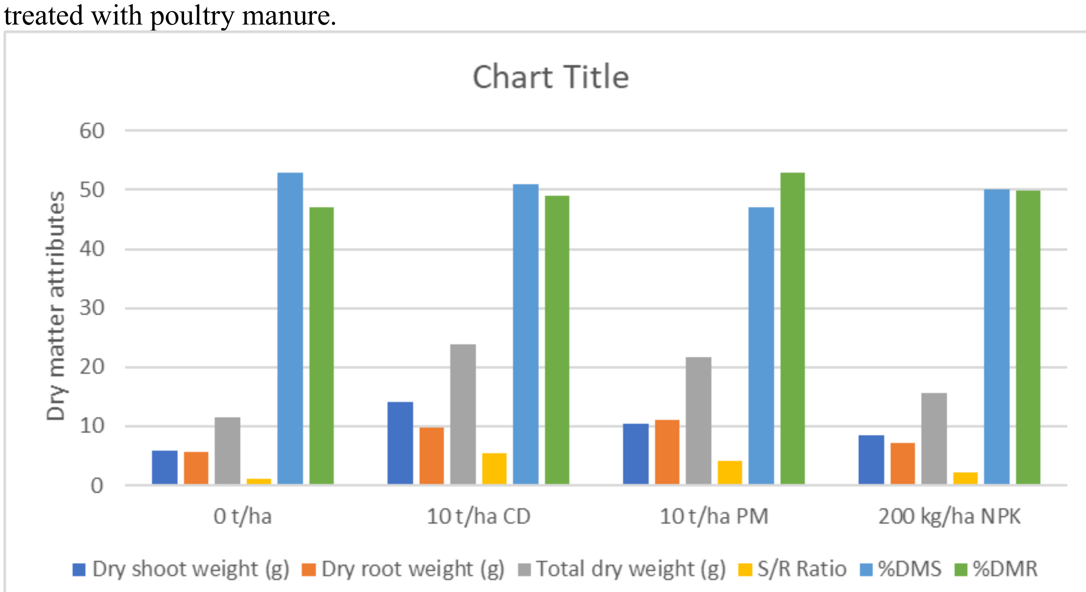

Figure 3: Dry shoot weight, dry root length, total dry weight, s/r ratio, %DMS, %DMS of carrot as influenced by different fertilizer sources. CD-Cow dung and PM-poultry manure, s/r ratio-shoot/root ratio, %DMS-percent dry matter distribution to the shoot and %DMR- percent dry matter distribution to the root.

CONCLUSION

It was evident that application of cow dung and poultry manure increased most of the traits evaluated in this study. Interestingly, application of poultry manure enhanced plant height, canopy diameter, root length, root diameter and root weight. Therefore, soil amendment using poultry manure is recommended for carrot growers in the study area.

ABSTRACT
This study provides an understanding to the relationship between climatic factors and sugarcane productivity in Eswatini. Two data sets were used for weather parameters, annual rainfall and average temperatures, this was obtained from the World Bank climate data portal, while sugarcane yield was obtained from Food and Agricultural Organization statistics database. The dataset spanned for a period of fifty-eight-year (1961-2018). The yield of sugarcane showed different variations over the period, with yield showing an increase in the first 14 years (1961-1975), and then showed a decreasing trend at a decreasing rate in the following 14 years (1976-1990), and then started decreasing at an increasing rate in the next 16 years (1991-2007) and in the last 10 years (2008-2018) the sugarcane yield was at a constant trend. The analysis of the observed weather records showed an increase in average temperatures and a decrease in annual rainfall in the observed fifty-eight-year period. The regression analysis of this study concluded that temperature was not significant and rainfall was significant at 1% level. The sugarcane trend was significant at 1%, and it showed that a point percentage change in the independent variables caused a percentage change of 0.017 in sugarcane yield in the long run. The adjusted R^2 of 0.373 indicated that 37.3% of the dependent variable (yield) was explained by the independent variables.
Keywords: *Climate change, Rainfall, Temperature, Sugarcane, Yield*

INTRODUCTION

In Southern Africa, where livelihoods and economies are extremely susceptible to weather fluctuations, climate extremes provide a significant challenge to resilience (United States Agency International Development, 2016). Climate change is likely to have negative impacts upon agricultural production, food security and economic development, especially in developing countries (Hannah *et al.,* 2005). Sugarcane is a climate vulnerable crop. The climate change, though, a very slow phenomenon is now accelerated due to natural as well as enormous human activities disturbing the composition of the atmosphere. The predictions of various climatic models for probable rise in temperature, rainfall show alarming conditions in the coming decades. As sugarcane is very sensitive to temperature, rainfall, solar radiations etc., a significant effect on its production and sugar yield is therefore, expected in future (Srivastava & Mahendra, 2012). The global production of sugarcane is anticipated to be significantly impacted by climate change, particularly in poorer nations due to their limited adaptive capacity, increased susceptibility to natural disasters, and inadequate forecasting and mitigation techniques. Increases in the frequency and intensity of extreme weather circumstances brought on by climate change may have had a detrimental impact on sugarcane production and will likely continue to do so (Zhao & Li, 2015).

Relative to the overall Swazi economy, the sugar industry is quite significant as reflected in the following statistics, sugarcane growing accounting for 74% of total agricultural output, employment in sugarcane growing contributing 35% to total agricultural wage employment, sugar milling employment compromising of 18% of total manufacturing wage employment, the sugar industry output (i.e. sugarcane growing plus milling) contributing 13% to GDP, sugar industry employment compromising 17% of total private sector wage employment and 10% of national formal sector employment and sugar exports contributing 16% to total export earnings (Swaziland Sugar Association, 2015). Therefore, it's critical to contribute to our understanding of the likely future climate, the distribution of impacts across various regions, the direct and indirect effects of these changes, and the best ways to adapt in order to lessen any potential negative effects on Eswatini's sugarcane production.

METHODOLOGY

The study was the Kingdom of Eswatini, a small, land-locked Kingdom in South-Eastern Africa. The Kingdom is bordered in the North, West and South by the Republic of South Africa and in the East by Mozambique. The country has an area of 17,364 square kilometers, and it has four distinct geographical regions, and also four has four ecological regions which consists of the Highveld in the North and West, with mountainous scenery and high rainfall, sloping east, through the intermediate Middleveld, to the dry, hot, and relatively flat Lowveld. The data used in the study was secondary data, information was collected from Food and Agricultural Organization statistics database (1961-2018). Data on monthly temperature and rainfall was obtained from the World Bank climate data portal (1961-2018).

Analytical techniques

Both descriptive such as mean and standard deviation, graphs and inferential (multiple regression analysis) statistics was used to analysed the set objectives of the study.

Multiple Regression Analysis Equation:

$Y_i = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + u$ ……………………………….(eqn 1)

Where:

Y_i = is yield (dependent variable)

β_0 = is the intercept

$\beta_{x\,=}$ slope of the coefficient

X_1 = average temperature

X_2 = annual rainfall

U = random error term

RESULTS AND DISCUSSION

Table 1 shows the descriptive statistics of the study. It shows that there were fifty-eight observations, which represents a period of fifty-eight years from year 1961 to 2018. The descriptive statistics describes the relationship between the dependent variable which is yield and the independent variables which are rainfall and temperature. The mean rainfall recorded was 807.81mm, the mean temperature was 20.15^{0}C and the mean yield recorded was 100.49 tonnes per hectare. The standard deviation value for rainfall was 167.77 mm, which is high (as a rule of thumb, a standard deviation >=1 indicates a relatively high variation, while a standard deviation <1 can be considered low) . This means that the values of the data are spread out over a wider range. Standard deviation for temperature was 0.51^{0}C, which is low. This means that the values of data set tend to be close to the mean (also called the expected value) of the set. Standard deviation for yield was 10.47 tonnes per hectare, which is high. This means that the values of data are spread out over a wider range. The minimum and maximum of rainfall were 524.78 mm and 1510.85 mm respectively. The minimum and maximum of temperature were 19.28^{0}C and 21.26^{0}C respectively. The minimum yield was 55.82 tonnes per hectare which was observed in the year 1963 and the maximum yield was 120.56 tonnes per hectare recorded in the year 1970. The median values for rainfall, temperature and yield were 787.34 mm, 20.16^{0}C and 120.56 tonnes per hectare respectively.

Table 1: Descriptive Statistics

Statistics	Rainfall	Temperature	Yield
Mean	807.81	20.15	100.49
Standard Deviation	167.77	0.51	10.47
Minimum	524.78	19.28	55.82
Median	787.34	20.16	99.23
Maximum	1510.85	21.26	120.56
No. of Observations	58	58	58

Source: Own computations of output from R

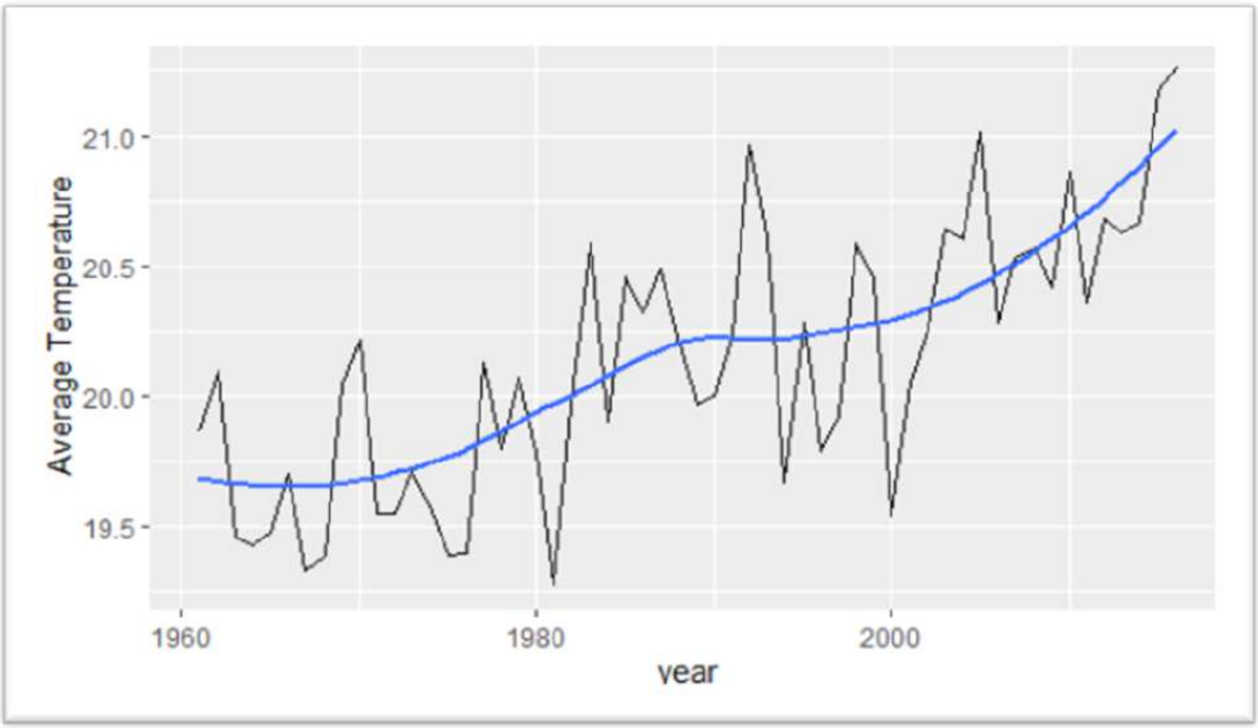

Figure 1: Trend graph of Temperature

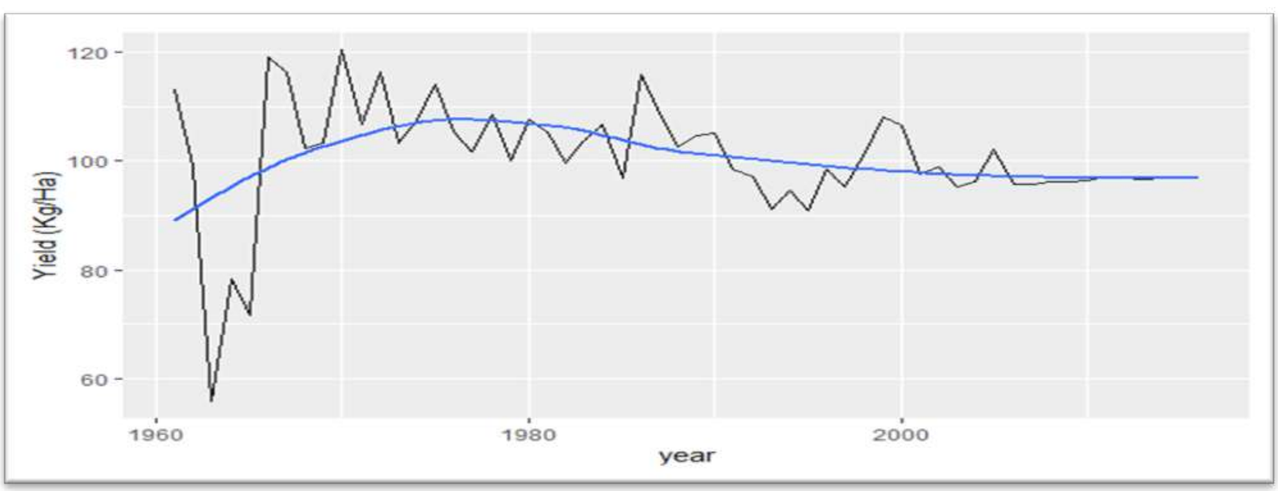

Figure 2: Trend graph of Sugarcane yield

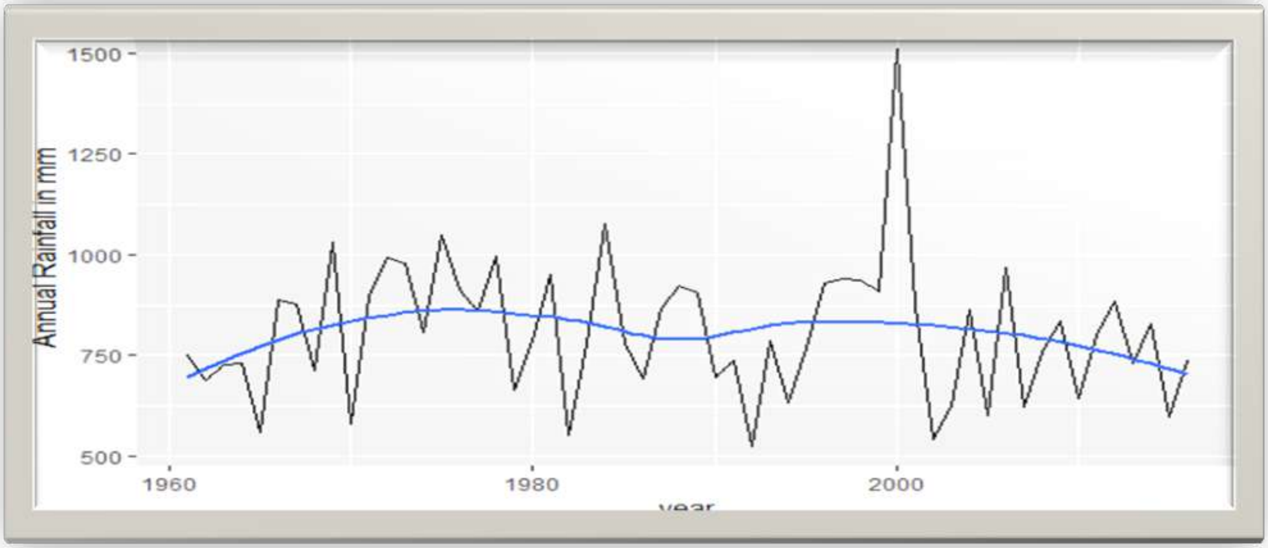

Figure 3: Trend graph of Rainfall

Table 2 presents the results of a regression analysis of yield as the dependent variable and rainfall and temperature being independent variables. The results of the regression analysis are shown as output in natural form (1) and in Log form (2). Results from the Log form (2) were used to make interpretations. This is done to improve linearity between the dependent and independent variables. It improves validity of statistical analyses. The regression analysis results indicated that temperature is not significant with a negative coefficient (-1.870). A point percentage change in rainfall leads to a 0.867 percentage change in sugarcane yield with a standard error of 0.276 at 1% significant level. The sugarcane trend is significant at 1%, showing the rate of change of the model, a point percentage change in the independent variables causes a percentage change of 0.017 in sugarcane yield in the long run. The constant intercept of (-0.529) indicates that holding all explanatory variables (rainfall and temperature) constant, the sugarcane yield is negative, the sugarcane yield decreases by 0.569.
The R^2 figure of 0.407 indicates that 40.7% of the variation in sugarcane yield was explained by the independent variables (rainfall and temperature) included in the model. Yield is determined by many independent variables which were not included in the regression model which include labour, fertilizers, pesticides and capital stock, and this can explain the low R^2.

	Dependent variable:	
	log(yield)

Source: output from R

CONCLUSION

General conclusions can be made on the basis of the analysis of sugarcane yield, average temperatures recorded and annual rainfall received over the fifty-eight-year period (1961-2018). From observing the line graphs that were presented, it can be seen that, firstly, sugarcane yield is somewhat at a constant trend with an average yield of 96 t/ha in the last 10 years of the years under review (2008-2018). Temperature is increasing with the highest peak being at 21.26^0C average temperatures recorded in 2016. The annual rainfall has been declining in the last fifty-eight years. From this, it can be concluded that the increasing temperatures cause water scarcity to also increase. The sugarcane crop demands more of the now scarce water resource because of the increasing temperatures which cause less rainfall which is useful for irrigation.

ABSTRACT
The consumption of organic product has been of assistance in the management of non-communicable disease and in the promotion of good health and extended life span. This study therefore analyses the drivers of adoption of organic farming among urban vegetable growers in Lagos State, Nigeria. Data were collected from the sampled respondents (farmers) in the selected communities of the study areas through a structured questionnaire with interview schedule. The study sampled a hundred and eighty-three urban vegetable growers in the study area. Both descriptive and inferential statistics (Logit regression model) was employed in analysing the data obtained. The findings of the study showed that average age of the farmers as 49.3; household size of 5; farm size of 0.13 hectares and farming experience of about 21 years. Logit model result showed that farm size, age, education, experience and household size were significant factors that affect the adoption of organic farming, the implication of these from the finding is that increase in the level of any of the explanatory variables with positive sign will have a positive effect on the likelihood of adoption of organic farming by the farmers. However, urban vegetable growers should be encouraged in order to increase organic productivity.
Keywords*: Agriculture, Logit, Organic, Urban, and Vegetable*

INTRODUCTION

Agriculture, one of Nigeria's primary economic sector makes a substantial contribution to the country's development. The government gives this industry top emphasis and attention before the advent and exploration of crude oil. Researchers believe that Nigeria might achieve the much-needed economic independence through organic agriculture at a time when people around the world are yearning for sustainable farming practices that protect the environment and give people access to wholesome food. Rapid output and productivity growth is essential for the agricultural sector to sustainably serve this pivotal role (Onche, 2010). The market for organic vegetable farming is predicted to grow at a compound annual growth rate (CAGR) of 4.9% from $7.41 billion in 2020 to $7.77 billion in 2021 (Baskaur, et al., 2021). This growth is primarily attributable to companies returning to business and adjusting to the new normal while recuperating from the COVID-19 impact, which had previously resulted in preventive control measures like social distancing, remote work, and the closure of commercial activities that created operational challenges.

Organic foods are becoming more popular and attracting higher premiums from consumers, providing a great opportunity to increase farmers' income and food security (Mishra et al. 2018; Yu et al. 2018). In promoting and enhancing food safety, sustainable agroecosystem, including biodiversity, biological cycles, and soil biological activity, organic agriculture (OA) is a comprehensive production management system that recognizes the need for locally adapted systems due to regional conditions and prioritizes the use of management practices over the use of off-farm inputs. This is achieved by fulfilling any specific function inside the system by cultural, biological, and mechanical processes whenever possible, rather than with synthetic materials. The goal of organic farming is to increase the soil's biological fertility so that crops may absorb the nutrients they require from the soil's constant turnover. This releases the nutrients in a form that is compatible with plant needs.

Low yield constrained adoption of OA when compared with the yields from conventional, intensive agriculture. This yield shortfall could be made up by increasing the organic land area (Seufert et al. 2012). There has been extensive research to identify the factors that improve farmers' adoption of OA (Adesope et al. 2012; Haris et al. 2018; Azam and Shaheen 2019; Liu et al. 2019; Cakirli and Theuvsen 2020; Hou et al. 2022). But little have been done as regards this in Lagos – an urban city where urban agriculture is gain momentum. It is on this note that this study

METHODOLOGY

The study was carried out in Ojo Local Government Areas in Lagos State. It is inhabited by mainly Aworis communities in the Riverine Area of Ojo Local Government includes Irewe, Taffi Hausa, Taffi Awori Itogbesa, Popoku while in the upland, settlements include Ojo, Ira, Ajangbadi, Sabo-Oniba,Ilufe, Igbede, Agric, Arufa, Olugbemi, Muwo and others. The Ojo indigenes are mainly farmers, mat weavers, fishermen, hunters and petty traders. The study employ multistage sampling procedure to select the respondents. The study selected 6 communities and 183 respondents were sampled from these communities who primarily engage in vegetable production. Structured questionnaire was administered to farmers in the study area through the use of interview schedule to obtain data. The primary data collected was then subjected to statistical analysis. Both descriptive and inferential statistical tools were used in the study to examine the set objectives of the study.

Logit model

Logit regression model is a binary response model and it was used to analyze determinants of adoption of organic farming among the vegetable growers in the study area. The dependent variable was binary as we have vegetable growers that adopt OA and those that never adopt. As the probability model, the probability increases (from zero to 1), the odds also increase from 0 to infinity. And if β is 'large' then as X increases the log of the odds will increase steeply (equation 1). The explanatory variables use in this study include: Farmers' personal information, farm specific variables and production information that influences adoption of OA. The mathematic model was presented in equation 1 below:

$$\log\left(\frac{\pi}{1-\pi}\right) = \alpha + \beta X \quad \text{...(1)}$$

And the explicit model is thereby expressed as:

$Y = \alpha + \beta_1X_1 + \beta_2X_2 + \beta_3X_3 + \beta_4X_4 + \beta_5X_5 + \beta_6X_6 + \beta_7X_7 + \beta_8X_8 + e$

Where, X_1= Gender (dummy); X_2= Farm size (hectares); X_3= Age of respondents (years); X_4=Experience (years); X_5= Household size (Number of people); X_6=Social organization (dummy); X_7 = Education (years) and X_8= Occupation (dummy);

RESULTS AND DISCUSSION

The summary statistics of some of the variables used was presented in Table 1. The table revealed that the average age of vegetable farmers in the study area stood at about 49 years, having average farm size of 0.13 hectare, the average family labour stood at 43.33 mandays and hired labour at 18.68 manday. The average years of education stood at 14.88; implying that most of the vegetable farmers had formal education and had at least secondary school education. The household size has a mean value of about 5 persons; implying hat most of the vegetable growers' household were moderate and this has serious implication on the well being of the household members.

Table 1: Summary Statistics

Variables	Description	apriori expectation	Mean (Std. Dev)
Age	Years	+/-	49.31(12.97)
Farm size	Hectare	+	0.13(0.008)
Family labour	Size of labour in Manday	+	43.33(10.23)
Hired labour	Size of labour in Manday	+	18.68(6.11)

Gender	Dummy; 1 = male; 0 = female	-	0.53(0.46)
Education	Years of schooling	+	14.88(2.36)
Experience	Years	+	21.25(9.23)
Occupation	Dummy; 1 = veg. farming; 0 = otherwise	+/-	0.07(0.01)
Social Organization	Dummy; 1 = Member 0 = Non-member	+	0.22(0.09)
Household size	Number of people eating from the same pot	+/-	5.21(1.34)
Dry season vegetable production	Dummy; 1 = Yes; 0 = No	+/-	0.13(0.07)
Wet season vegetable production	Dummy; 1 = Yes; 0 = No	+/-	0.28(0.08)

Source: Field Survey, 2023

Table 2 revealed that 78.14% of the vegetable growers adopted green manure crop selection and sowing timing. About 62% adopted crop residue management to check major pest and disease. For the selection of seed treatment with bio fertilizer for vigour growth, most (53.55%). Vermicompost application receive no adoption from more than 93% of the respondents when more than 77% of the respondents failed to adopt Vermicompost preparation method. Other, organic farming activities adopted include: Seed treated with bio fertilizer for disease control (87.98%), Seed treated with bio fertilizer for vigor growth (53.55%). The result implied that most of vegetable growers in the study area are aware of most of the OA activities and quite number of them practice them.

Table 2: Adoption of Organic Farming among vegetable growers

Variables	**Yes**	**No**
Adoption of green manure crop selected and sowing time	143(78.14)	40(21.86)
Crop residue managed properly to check major pest and disease	114(62.29)	69(37.70)
Seed treated with bio fertilizer for vigour growth	98(53.55)	85(46.45)
Seed treated with bio fertilizer for disease control	93(50.82)	90(49.18)
Sown resistant varieties for pest/disease control	161(87.98)	22(12.02)
Organic/solid waste management	167(91.26)	16(8.74)
Practiced crop rotation and shallow ploughing for weed control.	117(63.93)	66(36.06)
Vermicompost preparation method	42(22.95)	141(77.05)
Vermicompost application	11(6.01)	172(93.99)
Bio fertilizers purchased from authorized source	54(29.51)	129(70.50)
Adopted indigenous/traditional method for proper storage	127(69.40)	56(30.60)

Determinants of Adoption of Organic Farming

Table 3 examines the determinants of adoption of organic farming. The empirical estimation of the Logit analysis result as presented in Table 3 reveals a log likelihood of -57.56424. Table 26 reveals that farm size with odd ratio of -0.217 is negatively significant determinant of adoption of organic farming among vegetable growers in the study area. It shows that the higher the farm size, the less likely the respondents will adopt organic farming. Age is also a significant factor in the determinants of the adoption of organic farming among small scale farming in the study area. The coefficient of age (-0.596) is negative which shows that the older respondents are less likely to adopt organic farming, than the younger ones. Also, the coefficient of Education positively drives adoption of organic farming. Implying education directly influence the adoption of organic farming and therefore indicated that the higher the educational level of the respondents, the higher they likely adopt organic farming

Furthermore, the result revealed that farming experience positively related to adoption of organic farming among small scale vegetable farmers in the study area. The result in the table implies that the higher the experience of the farmer, the more likely they will adopt organic farming. And lastly, household size with positive sign and significant at 5% level of confidence; implies that the greater the household size, the more likely the farmers will adopt organic farming and vice versa. Due to drudgery nature of OA practices, vegetable farmers with larger households' size are likely to have more hands for labour utilization.

Table 3: Parameter estimates of adoption of Organic Farming among vegetable growers

Variables	Odd ratio	t-value
Constant	4.270	2.72
Farm size	-0.217	-1.85*
Family labour	0.299	-1.06
Hired labour	-0.161	-0.78
Gender	0.579	0.87
Age	-0.596	-2.33**
Education	0.518	-2.85***
Experience	0.163	2.27**
Occupation	-0.219	-0.50
Social Organization	0.467	0.91
Household size	0.106	2.42**
Log livelihood = -57.564		
Chi^2 = 10.31		

Source: Field Survey, 2023

The result presented on Table 4 shows the constraints faced by vegetable growers in the study area. The result revealed that 92.34% of the respondents indicated that land availability is a major constraint to vegetable production in the study area. More that 64% of the respondents also identify flooding as the major challenge in vegetable production in the study area. Since the study area is a riverine area of Lagos, so the chance of being flooded is high. Also, more than 56% of the vegetable growers claimed pest attack or infestation s another problem with vegetable production, meanwhile 42.07% identify theft as their challenges, a smaller proportion (16.94% and 13.66%) claimed that land abuse and unstable market are the major challenges with vegetable production in the study area respectively.

Table 4: Distribution of Respondents based on problem faced in Vegetable Production

Problem	Frequency	Percentage
Pest Attack	103	56.28
Theft	77	42.07
Land unavailability	169	92.34
Flooding	118	64.48
Land Abuse	31	16.94
Unstable market	25	13.66

* Response > 100% due to multiple choice responses

CONCLUSION

The study explores the drivers of adoption of organic farming in urban area using Lagos as a case study. The study employed a multistage sampling procedure to selected 183 vegetable growers in Ojo Local Government area of the state. Based on the findings deduced from the study area, it is concluded that: most of the vegetable growers in the study area were middle-aged people having at least secondary school education, though, they were operating a small scale enterprise.

ABSRACT
The study on the non-adoption of post-harvest management practices by cocoa farmers in Etung Local Government Area, Cross River State, Nigeria was carried out to identify the types of post-harvest management practices mostly adopted by the cocoa farmers, identify factors affecting the non-adoption of post-harvest management practices and highlight constraints affecting the non-adoption of post-harvest management practice by the cocoa farmers. Two hundred and thirty one (231) cocoa farmers were randomly selected from ten (10) wards of the Local Government Area. Descriptive statistics, binary logistic regression model and Likert scale rating were used as statistical tools to achieve the objectives of the study. The study addressed five research questions and objectives, and tested one hypothesis, which was stated in the null form as "there is no significant difference in the adoption of post-harvest management practices by cocoa farmers in the study area". The study adopted multi-stage purposive random sampling procedure to selected two hundred and thirty one respondents from the ten council wards in the area. Primary source of data was obtained with the aid of a structured questionnaire administered to respondents by the researcher. Data obtained were analyzed using descriptive statistics such as frequencies, percentages, mean and inferential statistics like independent t-test. The result from the study revealed that majority of the cocoa farmers practiced mostly pod breaking, fermentation, drying, and packaging while storage was less adopted. The result equally revealed that lack of labour, poor access to credit facilities and farm inputs, climatic factors, lack of extension agents, fluctuations of market prices of cocoa, wide spread of pests and diseases among others were the major constraints in the non-adoption of post-harvest management practices in the area. This therefore recommends that more attention should be paid to post-harvest management practices by cocoa famers in Etung Local Government Area as only 60% adoption of the highlighted practices were recorded, also, there should be deliberate effort to sensitize, enlighten or educate cocoa farmers on the significance of packaging and storage as integral parts of post-harvest management. The number one constraint faced by farmers is unsatisfied price of beans dictated by buyers. To cub this, farmers' association in the study area should enact strict rules restraining members from accepting any ridiculous pricing from the marketers with punitive measure melt on defaulters. Lastly, further research work should explore possibility of assessing the various drying techniques that farmers in Etung Local Government Area of Cross River State Nigeria are presently practicing.
Keywords: *Constraint, descriptive statistics, management practices, non-adoption, post-harvest.*

INTRODUCTION
Cocoa quality is determined by the post-harvest stage, which includes fermentation, drying, and oxidative processes (Vera-Montenegro, Baviera-Puig and Garcia-Alvarez-Coque, 2014). Postharvest losses in cocoa can range from diseases to unpicked pods, spillage, and germinated beans. Research on cocoa

fermentation processes is inconclusive, and adoption varies based on regional and production practices (Amoah, 2013, Papalexandratou et al., 2013). To ensure fine quality cocoa, postharvest management is crucial. Other factors determining post-harvest technology include cost and adoption ability. Processing factors can influence the transfer and adoption rate of technologies, and if not properly managed, can affect the quality and quantity of the processed product (Ekum, 2017). Postharvest loss, which can be up to 80% of total production (Fot, 2013), is a significant issue in Africa, with losses ranging between 20% and 40% (Abass, Ndunguru, Mamiro, Alenkhe, Mlingi and Bekunda, 2014). These losses impact the lives of millions of smallholder farmers, impacting food volumes and trade-in values. The World Bank reports that sub-Saharan Africa loses food grains worth about USD 4 billion annually (Zorya, 2011). The sustainability of cocoa production is critical, especially in rural communities where it provides income and employment. Good Agricultural Practices (GAPs) are technical recommendations and guidelines that address environmental, economic, and social sustainability for on-farm processes, resulting in safe and quality food and non-food agricultural products.

The Food and Agriculture Organization (FAO) warns that by 2050, the agricultural sector must produce 50% more food than in previous years in sub-Saharan Africa and South Asia to meet global food demand. With a projected population of 9.1 billion by 2050, 70% extra food production is needed (Godfray, *et al*, 2010; Hodges, Buzby and Bennett, 2011). However, one-third of the food produced, worth $1 trillion, is lost during postharvest operations. Researchers suggest adopting best postharvest management practices, such as new technologies and strategies, to reduce postharvest losses (FAO, 2013). This study aims to determine the post-harvest management practices of cocoa farmers in the Etung Local Government Area, Cross State, Nigeria. The research focuses on identifying the socio-economic characteristics, types of post-harvest management practices, and factors affecting their adoption. The study also analyzes socio-economic factors influencing non-adoption of post-harvest management practices and highlights the constraints faced by farmers. The hypothesis testing shows no significant difference in the adoption of post-harvest management practices. The study's significance lies in providing empirical data on post-harvest management practices, which could guide policy formulation and implementation.

MATERIALS AND METHODS

Study Area

Etung Etung Effraya carried out Afangideh Etung Etung Ikom Boki Ikom Akampka Ejagham Etung 1500mm Government Etung with its capital. Etung Okwongwo Oban is one of the eighteen local government areas of Cross River State. It is located in the central part of the state and lies between latitudes 5000°00°4° N and 6000°05° N and extends between longitudes 80°00°5° E and 9000â 05ââ E (Okongor, Afangideh and Obong, 2013). The Etung Local Government Area borders the Ikom and Boki Local Government Areas to the north, the Cameroon Republic to the east and Ikom to the west in the south of the Akampka Local Government Area. It also has a land area of 903.22 km2 (Ministry of Lands and Survey, 2008). It is inhabited by the Ejagham speaking people. Etung lies in the equatorial zone with average annual rainfall between 1500 mm and 3000 mm. During the rainy season, the average daily maximum temperature is 29 °C. While the daily maximum temperature during the dry season is 350°C. The Etung Local Government Area is part of the Cross River Rainforest, which today represents an important part of what remains as Nigeria's tropical forest (Okongor et al., 2013). The forest in Etung includes: (a) Okwongwo Division and (b) Oban Division of Cross River National Park. This ecological zone has the highest species composition of rare and endangered plants including trees, shrubs, herbs etc. in Nigeria. The predominant crops include cocoa, banana, plantain and Arvengia.

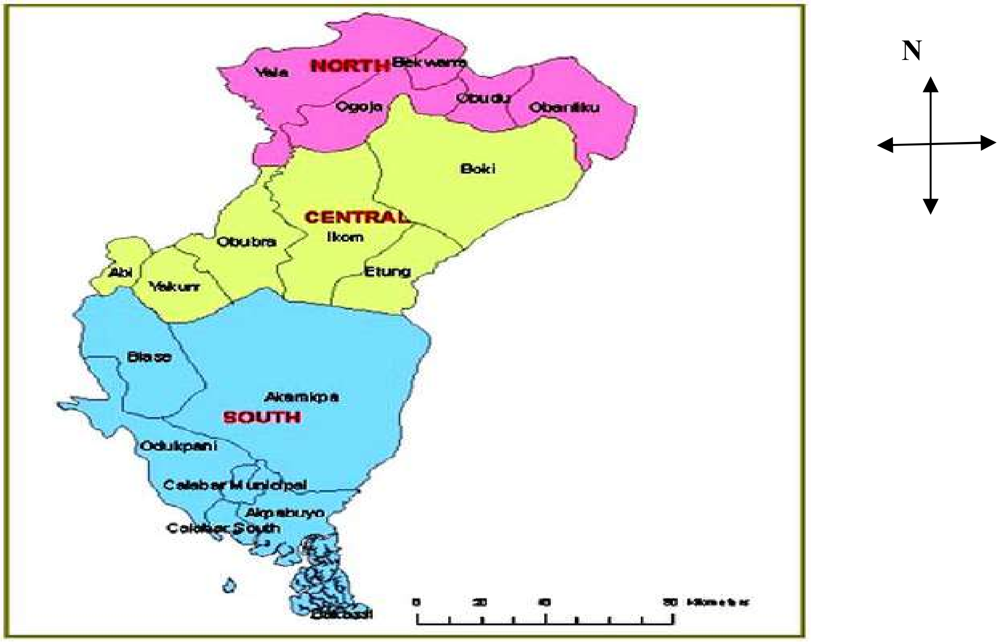

Fig. 1: Map of Cross River showing the study area, Etung Local Government Area
Source: Ministry of Lands and Survey, Etung Local Government land mass, 2008.

Population and sampling technique for the study

The population for this study consists of 2310 registered cocoa farmers in all ten (10) local government areas in Etung Local Government Area. A multi-stage purposive random sampling technique was used to select a total of two hundred and thirty-one (231) cocoa farmers using a proportionality ratio of 10% from the three thousand three hundred and ten (2,310) cocoa farmers registered with the Cocoa Farmers Association of Nigeria (CFAN), Cross River State Branch.

Table 1: Selection of sample size/respondents

Wards	Sample frame	Sample size
Abia	180	18
Abijang	40	4
Agbokim Obi	180	18
Ajassor	620	62
Bendeghe/Ekiem	180	18
Effraya	70	7
Etomi	460	46
Itaka	210	21
Mkpot	40	4
Nsofang	330	33
Total(10)	**2310**	**231**

Instrument of data collection, validity and administration of the research instrument, the main instrument for data collection is the questionnaire which was based on the objectives of the study to obtain information from the respondents. The instrument for this research, the questionnaire, was validated by my supervisor and other experts in the Department of Agricultural Economics and Extension and relevant corrections were strictly implemented. The instrument was then applied to sample participants in the study area with the help of two research assistants to improve speed and accuracy.

Measurement of Variables

The Likert four-point scales called Rating, namely; extremely severe, severe, moderately severe and non-severe were used to determine the limitations in post-harvest management practices by cocoa farmers in the local government area. It was also used to determine the extent to which each of the restrictions represents a restriction on cocoa production in the study area. To determine which of the variables was considered a critical impact or limitation, the variable mean of 2.50 was used. This was achieved by summing the assigned score to get ten and dividing the result by four (i.e. 4+3+2+1 = 10/4=2.50). Therefore, any variable with a mean of 2.50 and above was considered critical, while variables with less than 2.50 were considered not to have such a critical impact on the restriction. This method was used to address objective (V) of the research.

Data analysis

From the survey, the data was subjected to both descriptive and inferential analysis, to enhance its interpretation and discussion. Specifically, objective i, ii, iii and v were analyzed using descriptive statistics such as mean, tables, percentages and standard deviation. Objective iv was analyzed by using binary logistic regression. The implicit model of the multinomial regression is given as:

$Y = f(X_1 + \ldots X_n + u)$

Where:

Y = dependent variable (adoption of postharvest management practices: 1= adopted, 0= otherwise)

X_1 = age (years)

X_2 = sex (male=0, female=1)

X_3 = education (educated=0, 1=otherwise)

X_4 = years of farming experience (years)

X_5 = household size (number)

X_6 = size of farm (Ha)

X_7 = marital status (married =0, 1= otherwise)

u = error term; Objective V was achieved by using a four-point the Likert scale technique.

RESULT AND DISCUSSION

Socio-economic characteristics of respondents

The findings of analyzed data on socio-economic characteristics of the respondents in Etung Local Government Area are presented in Table 2.

Table 2: Distribution of respondents based on their socio-economic characteristics

Variables	Response categories	Frequency	Percentages	Mean
	<20	0	0.00	
	21-29	6	2.6

Source: Field data, 2022

Table 2 shows the distribution of respondents according to their socioeconomic characteristics. The results showed that about 45% of the study's respondents were 50 years old and older. Furthermore, 35.9% of them were between 40 and 49 years old. This means that many of the cocoa farmers in Etung Local Government Area are of advanced age. This also means that these farmers have many years of practical experience in cocoa management. In contrast, 16.5% and 2.6% were between 30 and 39 and 20 and 29 years old, respectively. The results in Table 2 showed that the majority (74%) of respondents were male and 26% were female. This result suggests that cocoa farming in Etung Local Government Area is a male-dominated activity, which may be due to the strenuous nature of cocoa farming. Regarding marital status, the majority (87.9%) of cocoa farmers were married, meaning that cocoa farming is largely run by family members. In addition, 11.7% are single and only 0.4% are widowed. This result also confirms the fact that cocoa cultivation is an important source of livelihood for farmers. The education level variables showed that the majority (57.6%) of the respondents had a university degree, 27.7% had a secondary school degree, 12.5% had a primary school degree and only 2.2% had no formal qualification.

This finding showed that cocoa farmers in Etung Local Government Areas are well educated, which could promote the adoption of improved management practices in agricultural activities. The results presented in Table 2 show that 19.5% of farmers had 1-10 years of experience in agriculture, 37.7% had 11-20 years of experience, 39.5% and 3.0% had 21-30 years or 31 or more years of experience. This result implies that the respondents have been involved in cocoa farming for several years. Table 2 also shows that 53.7% of respondents had a farm size between 1 and 5 hectares, while 35.5% had a farm size between 6 and 10 hectares. The cocoa production results show that 85.3% of respondents had a production of 0-5 tonnes/ha, 12.6% had a production of 5.1-10 tonnes/ha, while only a tiny fraction of 0.9 % of them had a production of 15.1 tons/ha above per year.

Types of post-harvest management practices in Etung Local Government Area

Table 3: Frequency distribution of the respondents based on types of post-harvest management practices available Etung Local Government Area

Practices	Yes (%)
Pod breaking	99.6
Fermentation	97.8
Drying	98.7
Packaging	88.7
Storage	43.3

Source: Field data, 2022

Table 3 shows that the majority of respondents adopted four different postharvest management practices. Specifically, 99.6% of respondents identified pod cracking as a management practice used by cocoa farmers in the study area. Furthermore, most farmers, namely 97.8%, recognized fermentation as a management practice used in the study area. Furthermore, most farmers (98.7%) reported that drying is one of the post-harvest management practices adopted by farmers in the study area. Again, many (88.7%) of the respondents stated that they use packaging as a post-harvest management practice in the study area. Only 43.3% of cocoa farmers agreed that storage is a post-harvest management practice, but they do not practice it. This result could be due to high costs of storage facilities or the availability of a year-round market for disposal of cocoa beans after packaging. This suggests that the post-harvest management practices most commonly practiced by cocoa farmers in Etung Local Government Area are pod breaking, fermentation, drying and packaging, while only a very small number of farmers (43.3 %) practiced storage as a post-harvest management practice.

Post-harvest management mostly adopted by the farmers

Table 4: Frequency distribution of the respondents based on non-adoption of post-harvest management practices adopted by farmers in the area

Practices	Not practiced	Low	Medium	High	Very high	Extremely high	SD	Mean	Remark	Ranking
Drying	0	35	14	44	67	71	1.379	4.54	Mostly adopted	1st
Pod breaking	0	63	31	50	34	53	1.515	3.93	Mostly adopted	2nd
Fermentation	0	50	63	47	57	14	1.233	3.66	Mostly adopted	3rd
Packaging	10	39	109	51	15	7	1.024	3.19	Less adopted	4th
Storage	113	17	16	7	14	64	2.194	2.93	Less adopted	5th

Source: Field data, 2022

This section of the study examined the post-harvest management practices adopted by cocoa farmers in the study area. Table 4 shows that three of the postharvest management practices were largely adopted by farmers. These three post-harvest management practices used are pod cracking, fermentation and drying. This confirms the Cocoa Research Institute of Nigeria (CRIN) observation that cocoa farmers usually carry out the cracking, fermentation and drying of the pods within a few days of harvest without any delay (CRIN, 2011). However, according to the results, drying came first, breaking the pods second and fermentation third. This means that farmers are more concerned with drying as part of these management practices. On the other hand, Table 4 showed that packing and storage were less applied post-harvest management practices in the study area.

Factors influencing the adoption of post-harvest management practices

Table 5: Results of the binary logistic regression of determinants of adoption of post-harvest management practices in Etung Local Government of Nigeria

S/N	Variables	Coefficient	Wald	Exp (B)	Sig
	Constant	4.571	6.291	96.644	0.012*
1	Sex (X_1)	-1.176	8.143	0.308	0.004**
2	Maritalstatus (X_2)	0.515	0.609	1.673	0.435^{ns}
3	Age (X_3)	-0.018	0.553	0.983	0.457^{ns}
4	Education (X_4)	0.074	0.086	0.928	0.769^{ns}
5	Household size (X_5)	0.276	0.436	0.759	0.509^{ns}
6	Farming experience (X_6)	0.026	1.033	0.974	0.309^{ns}
7	Farm size (X_7)	-0.014	0.105	0.986	0.745^{ns}
	Nagelkerke R^2	0.084			

Source: Field data, 2022 ns = Not Significant; *= Significant @ P<0.05; *= Significant @ P<0.01

Table 5 shows the results of the factors affecting non-implementation of post-harvest management practices by cocoa farmers in Etung Local Government Area. Due to the dichotomous nature of the dependent variable, this was determined using binary logistic regression. The model produced a Nagelkerke R-squared value of 0.084. This value, which is the pseudo R-squared, implies that only 8.4% of the variation in the dependent variable was explained by the adjusted independent variables. The result shows that gender (X1), age (X3) and farm size (X7) all had negative coefficients (-1.176, -0.018 and -0.014, respectively). This means that as these variables increase, the adoption of post-harvest management practices by cocoa farmers in the study area decreases. The odds ratio of these variables (0.308, 0.983, and 0.986, respectively) implies that a 1% increase in male farmers reduces the likelihood of them adopting post-harvest practices by 0.308 times. Furthermore, a 1-year increase in farmer age makes farmers 0.983 times less likely to adopt these practices, while a 1% increase in farm size makes them 0.986 times less likely to adopt post-harvest management practices -times less. This result contradicts the findings of Ewuola et al. (2010) and Wossen et al. (2013) who found that farm size has a positive association with technology adoption. On the other hand, marital status, education, agricultural orientation (full-time/part-time), and agricultural experience all had positive coefficients (0.515, 0.074, 0.276, and 0.026, respectively).

This result means that an increase in these variables consequently leads to an increase in the rate of adoption of post-harvest practices in cocoa production in the study area. Their odds ratios of 1.673, 0.928, 0.759, and 0.974, respectively, mean that married farmers are 1.673 times more likely to adopt postharvest practices. The odds ratio of education means that educated individuals are 0.928 times more likely to adopt post-harvest management practices in the study area. The odds ratio of agricultural orientation implies that farmers of this household size are 0.759 times more likely to adopt the practices, while the agricultural experience probability means that farmers with higher experience among cocoa farmers are 0.974 times more likely Likelihood of adopting post-harvest management practices production in Etung township area. However, among the adjusted variables, only gender (X1), albeit with a negative coefficient, was statistically significant at 0.01 alpha values and a P value of 0.004. This implies that gender is a crucial factor for non-implementation of post-harvest management practices in Etung Local Government Area.

Summary

The main purpose of this study was to ascertain the postharvest management practices carried out by cocoa farmers in Etung Local Government Area of Cross River State, Nigeria. The results of analysis of the socio-economic characteristics of the respondents revealed that about 45.02% of the respondents are 50 years and above, majority (74.0%) of the respondents were male. Majority (87.9%) of the respondents were married and most 57.6% of the respondents had tertiary education while only (39.8%) of the farmers had 1-10 years of farming experience. The result of cocoa output showed that (85.3%) of the respondents had an output of 0-5tons/ha. The findings also showed that majority (87.9%) of the respondents identified four different post-harvest management practices that they in the area. They are pod breaking, fermentation, drying and packaging. On the other hand, responses on the post-harvest management practices adopted by cocoa farmers in the study area showed that three of them were mostly adopted by farmers. These three adopted post-harvest management practices are pod breaking, fermentation and drying. The binary logistic regression analysis of the factors influencing the non-adoption of post-harvest management practices revealed thatsex (X1) age (X3), and farm size (X7), all had negative coefficient, while marital status (X2), education (X4), farming orientation (full time/ part time) and farming experience (X6) all had positive coefficients. However, only sex (X1) was statistically significant at 1% probability level. Information on the distribution of respondents based on constraints faced by farmers in the adoption of post-harvest management practices in cocoa farming revealed that unsatisfied price of beans imposed by buyers (ranked 1st), Lack of access to inputs (ranked 2nd), and Lack of extension agents' visitation (ranked 3rd) were the most critical constraints faced by farmers Etung Local Government Area.

CONCLUSION

The adoption of publish-harvest management practices amongst cocoa farmers in Etung nearby government location cannot be over emphasized, having a right away impact on the productiveness of the cocoa farmers. Proper adoption of these control practices can save you wastage, increase yield and in the end consequences in higher earnings for the farmers. From the take a look at, majority of the humans in Etung are dependent on cocoa production as their supply of livelihood. As a consequence, publish-harvest mismanagement can be very catastrophic and debilitating. From this look at, it can be concluded that majority of farmers adopt submit-harvest control practices along with pod breaking, fermentation and drying. Thus, those practices may have far greater developmental effect at the cocoa price chain and farmers' productivity when further harnessed.

RECOMMENDATIONS

i. More emphasis should be devoted to post-harvest management methods by cocoa farmers in Etung since only 60% adoption of the highlighted measures were documented, according to the study's findings.
ii. There should be a concerted effort to inform, educate, and sensitize cocoa farmers on the value of storage and packing as crucial elements of post-harvest management.
iii. The biggest obstacle for producers is the unfavorable price that purchasers set for their beans. Farmers should create stringent regulations prohibiting members from accepting any absurd pricing from the marketers and put a melt on defaulters to stop this.

ABSTRACT

The study examined the economic analysis of water melon marketing in Oriire Local Government Area, Ogbomoso, Oyo State. The study specifically described the socio-economic characteristics of watermelon marketers, estimated the cost and returns in watermelon marketing, identification of marketing outlets as well as describing of the constraints to watermelon marketing in the study area. A multi-stage sampling technique was employed in selecting 120 respondents for this study. Data collected were analyzed statistically with descriptive and budgetary analysis methods. This involved the use of tables, frequency counts, percentages and mean values. Inferential statistics such as multiple regression model and estimated with OLS was used for the study. Budgetary analysis Gross Margin (GM), Benefit cost ratio was used in determining of the profitability of water melon marketing. The results indicated that over 91.67% of the respondents were between the active ages of 25 and 50 years. About 98.34% had household size of between 1–10% persons. Substantive percentage (58.33%) of the respondents had no formal education. About 90% had 2– 9 years of marketing experience. The budgetary analysis results indicated that watermelon marketing had an average total revenue of #105,200, with #29, 105 as total cost of marketing, and the Gross margin was #77,869. Finally, the major problems associated with watermelon marketing identified by the respondents in the study area were lack of price regulation policy, price fluctuation, poor access to credit, poor storage, distance to market and theft of product. It recommended that both formal and informal financial institutions should be encouraged by the Government to provide financial assistance watermelon farmers so that they can expand and improve their existing business volume.

Keywords: *watermelon, marketing, budgetary, regulation farmers*

INTRODUCTION

Watermelon (*Citrullus vulgarus*) belongs to the family cucurbitaceae, extensively grown both in the tropics and temperate regions. The crop is a native of tropical Africa and has been grown in West Africa for many centuries (Sinnadurai, 1992). Watermelon is a warm season crop, which requires continuous warm temperatures during the entire growing period. The crop prefers a sandy loamy soil with pH of 5.8 to 7.2, while its cultivation in heavy textured soils results in a slower crop development and cracked fruits. The recommended fertiliser rates for higher production are 80 to 100kg/ha N, 25 to 60kg/ha P and 35 to 80kg/ha K (FAOSTAT, 2001). Worldwide, the yield of watermelon averages about 25 t/ha, varying from 5 – 60 t/ha, depending on cultivars and cultural practices. The maximum and minimum temperature for its growth ranges from about 35oC and 18oC respectively. The crop has an optimum soil temperature range of 20oC to 35oC (FAOSTAT, 2001). Warm dry spells are essential during fruit maturity to increase the sweetness of the fruit. High humidity not only decreases sweetness, but also reduces yield and tends to promote excessive vegetation growth (Sinnadurai, 1992). The length of the total growing period ranges from 80 to 110 days, depending on climate (FAOSTAT, 2001).

Watermelon (*Citrullus lanatus*) is a native of tropical Africa, where it has long been used by the wild tribes. It came to India by the fourth century AD. The sweet juicy *pulp* of the ripe fruit is eaten fresh.

Watermelon is a valuable alternative to drinking water in desert areas. Watermelon is relished by many people across the world as a fresh fruit. This is because it is known to be low in calories but highly nutritious and thirst quenching; it also contains vitamins C and A in form of the disease-fighting beta-carotene. Lycopene and betacarotene work in conjunction with other plant chemicals not found in vitamin/mineral supplements. Potassium is also available in it which is believed to help in the control of blood pressure and possibly prevent stroke (Adekunle *et al.*, 2005). Production of staple crops like cereals, yam, cassava, cash crops and some vegetables can contribute positively in Nigerian economy and result of this the problem of poverty, hunger and malnutrition could be alleviated and adequate (Mohammed, 2011). Production of exotic vegetables generates higher profit, employment and income to farmers than indigenous vegetables (Ajewole and Folayan, 2008). According to Adeoye *et al*. (2007) watermelon has an important place amongst the all exotic vegetable and sales in Ibadan Metropolis of Oyo State, Nigeria.

Research Questions

(1) What are the socio-economic characteristics of water melon marketers in the study area?
(2) What are the marketing practices of the respondents?
(3) What are the cost and returns associated with water melon marketing?
(4) What are the challenges faced by water melon marketers in the study area?

Objectives of the Study

The major objective of this study is to analyze the water melon marketing in Oriire Local Government Area of Oyo State.

Specific objectives are to:
(1). identify the socio-economic characteristics of water melon marketers in the study area;
(2) investigate marketing practices of the respondents;
(3) estimate the cost and returns associated with water melon marketing;
(4) identify the challenges faced by water melon marketers in the study area.

METHODOLOGY

Study Area

The study was conducted in Oriire Local Government Area of Oyo State. Oriire local government has her headquarter in Ikoyi-Ile. It is located around latitude $8^0 30^{'}$N of the equator and longitude $3^0 54^{'}$S of the Greenwich meridian. It is regarded as a derived savannah vegetation zone and a low land rainforest area. A fairly uniform temperature with annual mean temperature of 26^0C, lowest temperature of 24.3^0C while the highest temperature is 28.7^0C, mean annual rainfall is 1247mm it is long wet in middle March-July, heavy rain and high humidity period, short dry in August and short wet between September and October. The population of Oriire LGA was estimated to be 150628 (that of male was 76335, while female was 74293).Oriire Local Government Area is in derived savanna climatic zone where agricultural products such as yam, melon, cashew, mango, shea butter, cocoa, kola nut, palm-oil can be found. Therefore, most of the inhabitants engage in farming as their major occupation while some are hunters, traders, fish farmers, etc. In the relatively recent times charcoal production has also become a popular occupation of many households in the area. The area extends from Ipeba river along Oyo-Ogbomoso road to Doogo junction near Igbeti, Oyo state Nigeria. It covers a total estimated land area of 2,040 km^2, inhabiting over 100 communities such as Tewure, Iluju, Apiko, Saamo, Igbori, Odun-Ifa and Olokoto among many others .The population is predominantly Yoruba.

Population of the Study

The population of this study included all the watermelon marketers in Oriire Local Government Area, Oyo State.

Sampling Procedure and Sample Size

A multistage sampling technique was adopted to select respondents for this study. The first stage involved random selection of fifty Percentage (50%) of the total number of wards in the Oriire local government area. This implies that five (5) wards were selected out of ten (10) wards in Oriire Local Government

Area. The second stage involved random selection of two villages from each of the selected wards. The third stage involved selection of nine watermelon marketers from each of the ten villages, using cluster sampling technique. The sample size was 90 watermelon marketers for the study.

Method of Data Collection

The data for this study was obtained from primary source with the aid of a structured questionnaire based on the objectives of the study.

Data Analysis

Descriptive Analysis

This will involve the use of tables, Frequency counts, Percentages and mean values. This was used to analyze specific objectives 1, 2 and 4.

Budgetary Analysis

Gross Margin (GM) was used in estimating the profitability of watermelon marketing (Specific objective 3). It was calculated as difference between Total Revenue (TR) and Total variable cost (TVC).

TR was quantified as: quantity of watermelon sold × price per unit.

TVC was quantified as total cost of all variable inputs like purchase at farm gate, transportation, labour, etc.

Gross margin = Total Revenue – Total variable cost; GM = TR – TVC

Benefit cost ratio (BCR) is a ratio to determine the profitability of the watermelon.

$= \Sigma TR / \Sigma TVC$

If the BCR < 1, the business is not profitable; If the BCR > 1, the business is profitable

1. Cost and return analysis was performed as follows:
   a. Revenue: TR = P x Q, where TR = Total Revenue, P = Price of output and Q = Quantity of output
   b. Cost: TC = FC + VC, where TC = Total cost, FC = Fixed cost; and VC = Variable cost
   c. Profit: NP = TR – TC, where NP = net profit.
2. Revenue/cost ratio: R/C ratio is a ratio of total revenue to total cost used to understand the profitability of marketing operations. The criteria are as follows: R/C > 1 = profitable, R/C = 1 = neither profitable nor loss, and R/C < 1 = not profitable.

OLS Model Specifications

Inferential statistics such as the Ordinary Least Square regression (OLS) was used to test the study hypothesis. The model is thus specified below:

$Y = a + b_1x_1 + b_2x_2 + b_3x_3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots.. b_6x_6$

Where: Y = Revenue from watermelon sales (₦)

X_1 = Cost of watermelon (farm gate price) (₦)

X_2 = Labour cost (₦)

X_3 = Cost of transport (₦)

X_4 = No of years spent in school

X_5 = Years of experience

X_6 = Age (years)

RESULTS AND DISCUSSION

Socio-Economic Characteristics of the Respondents

Age of Respondents

Table 1 showed that most of the sampled marketers (40.83%) were between the ages of 31-40 years of age. Furthermore, 39.17% of sampled traders lie within the age bracket of 41-50 years and 11.67% below 30 years of age. This implies that watermelon marketing enterprise in the markets sampled is dominated by middle-age farmers who are still active with the mean age of 40 years and this has effect on agricultural production, marketing and constitute the working force of the populace to accomplish the tedious task of taking watermelon from the farm gates to the markets.

Table 1: Distribution of respondents by Age

Age group	Frequency	Percentage
<=30	14	11.67
31-40	49	40.83
41-50	47	39.17
51-60	10	8.33
Total	120	100.00

Marital Status of Respondents

Table 2 indicates that most of the watermelon marketers in the study area were married (87.50%) while only 6.67% were single. This suggests that watermelon marketing in the study area is dominated by married couples. This is attributable to the fact that watermelon marketing is a profitable venture, which can serve as a reliable source of livelihood for the family.

Table 2: Distribution of respondents by Marital Status

Marital status	Frequency	Percentage
Single	8	6.67
Divorced	1	0.83
Widowed	2	1.67
Separated	4	3.33
Married	105	87.50
Total	120	100.00

Educational Background

Table 3 shows that 58.33% of the sampled respondents had no formal education, 26.67%% had primary school education, while only 15.00% of the sampled respondents had secondary education. This finding agrees with Adekunle et al. (2009) who reported that most marketers in Nigerian rural areas are limited in terms of formal education. Hence, many rural dwellers who are presently active participants in the market channels have little educational qualification since they could not see it as prerequisites.

Table 3: Distribution of respondents by educational status

Education status	Frequency	Percentage
No formal Education	70	58.33
Primary Education	32	26.67
Secondary Education	18	15.00
Total	120	100.00

Experience of Respondents

Table 4 reveals that 50.83% of the sampled respondents have less than 5 years of experience, while 49.17% have between 6-10years of experience. This shows that the people are moderately experienced with the mean experience of 6years in the trade, a knowledge which would enable the marketers understand the intricacies of the trade and thus know how to cut down on marketing cost while attempting to maximize profit. Also, experience has been shown to enhance more efficient use of scarce resources by small holders in Nigeria

Table 4: Distribution of respondents by Marketing Experience

Marketing experience	Frequency.	Percentage
<=5	61	50.83
6-10	59	49.17
Total	120	100.00
Mean: 5.38 years		

Household size of Respondents

Table 5 revealed that 49.17% of the respondents had household size ranging between 6-10 members and not more 5 members respectively, while only 1.67% had household size more than 10 members. The mean household size was 6members. This implies that most of the marketers in the study area had a considerable household size.

Table 5: Distribution of respondents by Household size

Household size	Frequency	Percentage
<=5	59	49.17
6-10	59	49.17
Above 10	2	1.67
Total	120	100.00

Mean: 6.00 members

Membership of Association

Businessmen and women normally belong to one marketing association or another. Table 6 revealed that high Percentage (73.33 %) of the watermelon marketers belongs to a social group association, while 26.67% of the respondents do not belong to any association.

Table 6: Distribution of respondents by members of Association

Group	Frequency	Percentage
Yes	88	73.33
No	32	26.67
Total	120	100.00

Religion of Respondents

Table 7 indicates that 52.50% of the watermelon marketers in the study area were Christians, 46.67% were Muslims while only 0.83% was a traditional worshipper.

Table 7: Distribution of respondents by their religious

Religion	Frequency	Percentage
Christianity	63	52.50
Islam	56	46.67
Traditional	1	0.83
Total	120	100.00

Marketing practices of the respondents

Table 9 reveals that 92.50% of the sampled respondents sell their watermelon to wholesalers, 60.00% of the respondents use sale agents to sell their watermelon, 60.00% also sell their watermelon to commercial city centers, 85.83% of the respondents sells their watermelon to the retailers while only 45% of the water melon marketers sampled sells to schools and organized bodies.

Table 8: Marketing sales outlet of the respondents

Sales Outlets	Frequency	Percentage
Wholesale	111	92.50
Agent	72	60.00
City sale	72	60.00
Retail sale	103	85.83
Organized body sale	54	45.00

Budgetary analysis

Marketing expenditure; Cost of Parking, Purchase cost, Labor cost, transport cost, and agent cost constituted Variable Cost with an average value of #27, 330 and with a Total Fixed Cost of #1959 The average Total revenue of #105,200. Watermelon marketing is profitable with a gross marketing margin of #76094.57 and a net margin of #76094.57

Table 9: Distribution of respondents by Budgetary Analysis

Parameters	Cost (#)	Value (#)
Total Revenue		105200
Variable cost		
Cost of parking	6575.833	
Purchase cost	5771.667	
Labor	8100	
Transportation		5858.333
Agents		1025
Total variable cost (TVC)	27330.83	
Total fixed cost	1959.184	
Total cost (TVC+TFC)	29105.43	
Gross margin (TR-TVC)	77869.17	
Net margin (GM-TFC)	76094.57	

Challenges faced by water melon marketers

Marketing of watermelon in the study area within the period of this survey is not without constraints. The major constraints observed during the study are ranked and presented in Table 4.11. Lack of price regulation policy, Price Fluctuation, Poor access to credit, Poor storage, Distance to market and Theft of product were the most prominent constraints of watermelon production in the study area.

Table 10: Challenges Associated with Watermelon Marketing

Challenges	Frequency.	Percentage	Rank
Poor storage	118	83.33	4
Price fluctuation	109	90.83	2
Poor market access	51	42.50	7
Seasonal Availability	46	38.33	8
Poor patronage	24	20.00	9
Distance to market	99	82.50	5
Theft of product	94	78.33	6
Poor access to capital	106	88.33	3
Lack of Price regulation	114	95.00	1

Summary
The broad objective of this study is to examine the economics analysis of watermelon marketing in the study area. The specific objectives were to describe the socio-economic characteristics of watermelon marketers, estimate the costs and returns in watermelon marketing, to identify the marketing outlets and describe the constraints to watermelon marketing in the study area. To achieve these objectives, primary data were collected with aid of questionnaire administered on the respondents. A multi-stage sampling technique was employed in selecting the respondents for this study. A total of 120 watermelon marketers formed the sample size for the study and each respondent was interviewed. The analytical tools used to analyze the data included, descriptive statistics and budgetary analysis. The results indicated that over 91.67% of the respondents were between the active ages of 25 and 50 years. About 98.34% had household size of between 1–10% persons. As high as 58.33% of the respondents had no formal education. About 90% had 2– 9 years of marketing experience. And 70% of the respondents were Hausa.The Budgetary analysis results indicated that watermelon marketing had an average total revenue of #105,200, with #29, 105 as total cost of marketing, and the Gross margin was #77,869. Finally, the major problems associated with watermelon marketing identified by the respondents in the study area were Lack of price regulation policy, price fluctuation, poor access to credit, poor storage, distance to market and theft of product

CONCLUSION
It may therefore be concluded that:

- **i.** the mean age of the water marketers was 40 years of age,
- ii. the level of education is low as only 33% of the watermelon marketers had a formal education
- iii. Most marketers had only 1-7 years' experience due to the newness of the crops in southwestern markets and most of the actors in the market are Northerners.
- iv. The functional outlets of watermelon sale included wholesale, retail, commercial cities and organized bodies
- v. The cost and return analysis revealed that watermelon marketing in the study area was profitable
- vi. The problems encountered by the farmers are insufficient capital, lack of proper storage facility and inefficient transport services.

RECOMMENDATIONS
Based on the findings of the study it is recommended that:
The government and non-governmental organization should make efforts towards improving rural road conditions in Nigeria, and also construct rural feeder roads that will go a long way at reducing marketing costs, reduce the damages caused by poor roads and also stabilize the price of watermelon and therefore enhance the marketing of not only watermelon, but also many agricultural products.
In order to solve the problem of financial inadequacy facing the watermelon marketers, both formal and informal financial institutions should be encouraged by the Government to provide financial assistance to them so that they can expand and

ABSTRACT
*The study assessed the information need of Tomato farmers in Oyo Agricultural Zone of Oyo State. The study assessed the agricultural information needs (agronomic practices, economic, technical collected and legal information) of Tomato farmers in the study area. Multistage sampling technique was used to select 189 respondents for this study. Data for this study were collected with the aid of a pre-tested questionnaire. Statistical analytical tools used included descriptive and inferential statistics. Descriptive statistics used included frequency count, percentages and means while the inferential tool used was regression analysis. Majority of the respondents were male (76.7%), married (90.5%) with a mean age of 51 years and an average of 6 years in their formal education. Sources of information which was ranked highest by the farmers on Tomato were extension agent, other farmers and personal experience with Mean ($\bar{x}$) of 3.51 respectively. Storage techniques was ranked the most frequently needed technical information. The weather forecast/drought was ranked the most frequently needed legal information. The marketing of produce and farm management were ranked the most frequently needed economic information. The information seeking behaviour is motivated purposely to improve general knowledge on Tomato production (100.0%). The result of regression analysis model revealed that age of the respondents (t = 5.60***), years spent in school (t = 8.91***) and output from Tomato production (t = 2.20**) were significantly related with respondents' information needs on Tomato production. It was therefore concluded that respondents were in dire need of information on Tomato production. Training should be given to farmers especially in the areas of agronomic practices, technical, legal and economic information of Tomato production to cater for their information needs for improved performance of Tomato farmers.*
Keywords: *Assessment, Information, Need and Tomato Farmers*

INTRODUCTION

Regardless of one's level of expertise in a given industry or job, a person requires a variety of information to succeed (Abdullahi, 2015). Case (2002) described information need as an individual's or group's desire to locate and obtain information to satisfy a conscious or unconscious need. However, Ekoja (2010) explained that information needs are the information, which information seekers require to conduct their businesses and live their daily lives. The identification of information needs of a person will lead to the means of seeking for that information. Information users need information for solving problems, create awareness, recreational purposes and for up-dating of their knowledge. Information need is construed in the sense of data or a set of data specially required that will enable the user to make an appropriate decision on any related problem facing him or her at any particular time (Solomon, 2002). Information needs and seeking behaviour is for all categories of people be they urban or rural. However, Rafea (2009) reiterated that there is a general lack of relevant and accurate information on production practices, farm management, prices of agricultural produce and markets for agricultural products especially Tomato that can better the lots of farmers. This development had often times lead to pre and post-harvest losses in Tomato production leading to low returns to investment which will invariably affect the standard of living in the study area. The effect of poor post-harvest practices increases production wastages and lowers marketing efficiency. Conversely, reduction in post-harvest losses especially through adequate access to relevant information will more likely increase food availability hence, alleviation of lack of food problems. In view of the above, the objective of the study was to assess farmers' information needs on Tomato production in Oyo Agricultural Zone of Oyo State.

The specific objectives were to:-

1. describe the personal characteristics (socio-economic and enterprise) of Tomato farmers in the study area;
2. identify the available sources of information on Tomato farmers and;
3. investigate the areas of agricultural information needs (agronomic practices, economic, technical and legal information) of the Tomato farmers in the study area.

METHODOLOGY

The study was carried out in Oyo Agricultural zone of Oyo State. The population of the study included all the Tomato farmers in Oyo Agricultural Zone of Oyo State. Multistage sampling technique was used in the course of this research. Firstly, purposive sampling technique was used to select Oyo Agricultural Zone as the study area for this research since the zone is known to be high producer of Tomato due to favourable climatic condition (Babalola *et al*., 2010). Secondly, proportionate sampling technique was used to select fifty percent (50%) of six (6) blocks in the study area. This implies that three (3) blocks (Atiba, Iseyin and Afijo) were selected for this research in the study area. The third stage involved random selection of five villages from each of the selected blocks, that is, Atiba (villages selected: Agbaakin, Eleke, Falose, Iyalamu and Otefon), Iseyin (villages selected: Aba Tuntun, Aba Sule, Alagbede, Idi Igba and Igbo oloro) and Afijo (Imeleke, Laperi, Imini, Elewebe and Eleko). From the list obtained from the Oyo State ADP, Atiba LGA has an estimate of 134 households, 118 households in Iseyin and 120 households in selected villages in Afijio ADP blocks (OYSADEP, 2007).

The last stage involved systematic sampling selection i.e systematic sampling technique of one household head per household at fixed period interval of every two households. The sample size for this research was 189 Tomato farmers. Data for this research was collected from both primary and secondary sources. Primary data were collected with the aid of a pre-tested structured questionnaire. The statistical analytical tools that was used for this study included descriptive and inferential statistics. Questionnaire was analyzed through Social Science Statistical Package (SPSS). The descriptive tools used include frequency distribution, percentage, mean, standard deviation and mean ($\bar{x}$) while the inferential tool used was regression analysis model to test the hypothesis of the study.

Specification of regression model

Linear regression model was used to capture hypothesis 1. The independent variables were included in model are as follows.

$Y = f(X_1, X_2, X_3, X_4, X_5, X_6)$ ………… ……………………..(2.1)

where:

Y = (Score of information needs on Tomatoes production)

X_1 = Age (years)

X_2 = Years spent in school (years)

X_3 = Sex (1=male, dummy =0)

X_4 = Household size (actual members in the households)

X_5= Farm size of land (ha)

X_6 = Output of Tomato (kg)

RESULTS AND DISCUSSION

Personal Characteristics of Respondents

Table 1 shows the distribution of the respondents by sex. It was revealed that 76.7 percent of the respondents were male while 23.3 percent were female. The distribution therefore indicates that male farmers dominate Tomato production in the study area. The reason for dominancy of male in the Tomato production may be due to drudgery associated with farming activities. Male seem to have more access to production assets thereby motivating gender differential in the farm outputs and other inherent opportunities. The findings therefore indicates that gender may have a significant influence on adoption of some technologies. Gender affects technology adoption since the head of the household is the primary decision maker and men have more access to and control over vital production resources than women due to socio-cultural values and norms (Mignouna *et al*., 2011).

Table 1 shows the distribution of the respondents according to their marital status. Based on the distribution in the Table 4.1a, Also, 90.5 percent of the respondents were married, 5.8 percent of the respondents were single. The findings therefore indicate that majority of the respondents were married which could help boost their production level especially through unpaid labour supply from household members. This development will more likely reduce cost of production with attending increased savings. The finding conforms with the study of Oose *et al*. (2015) found that majority (86.9%) of their respondents were married. The mean age of the respondents was found to be 51 years which implies that most of the respondents were still active enough to participate in Tomato production. This finding agreed with Bamigboye and Kuponiyi (2013) which opined that majority (65.0%) of their respondents were within the age group of 40 and 59 years

The respondent mean years of schooling was 6years. The findings therefore revealed that most of the respondents had formal education although majority had low level of education. It is envisaged that this which will help boost adoption of improved technologies especially in Tomato production and storage for quality productions and high premium. The present finding is in line with previous studies (Mignouna *et al*., 2011) which opined that education level of a farmer increases his ability to obtain; process and use information relevant to adoption of a new technology. Similarly, Invwieri (2007) opined that, rural people (farmers) who are mainly illiterate require access to appropriate information to be able to make decisions and participate fully in the national development processes, including agriculture.

Table 1: Distribution of Respondents according to their Personal Characteristics (n = 89)

Personal Characteristics	Frequency	Percentage	Mean
Sex			
Male	145	76.7	
Female	44	23.3	
Marital Status			
Single	11	5.8	
Married	171	90.5	
Widowed	5	2.6	
Separated	2	1.1	
Age (Years)			
Less or equal to 30	18	9.5	
31-40	38	20.1	
41-50	47	24.9	
51-60	33	17.5	
Above 60	53	28.0	**51 years**
Years spent schooling (years)			
No Formal Education	39	20.6

3.1-≥5.0			
1-50	59	31.2	
51-100	118	62.4	71.9 baskets
101-150	12	6.3	

Sources of information on Tomato production

Table 2 presents the distribution of respondents by sources of information on the Tomato production. Based on the frequency of use of sources of information on Tomato production, extension agent, other farmers and personal experience were ranked highest with a Mean ($\bar{x}$)of 3.51 respectively. The findings therefore indicate that most respondents utilized diverse media to access information on Tomato production but with varying level of utilization. This may be due to the fact that these sources of information are more readily accessible, reliable with local content characteristics and that the authenticity of these sources had been tested over years. The finding is in concordance with that of Bitagi and Akor (2011) which analyzed information availability and Agricultural Productivity of Rural Farmers in Niger State and found that rural farmers in Niger State obtained information about farming activities from within themselves.

Table 2: Distribution of respondents according to available sources of information on Tomato farmers

Sources	Availability		Frequency of use of sources of information	
	Frequency	Percentage	$\bar{x}$	Rank
Extension agent	143	75.7	3.51	1st
Radio	68	36.0	3.46	6th

$\bar{x}$ - Mean

Agricultural information needs on Tomato production

The agricultural information need was categorized into four according to information needs on Tomato production. This aspect was divided into agronomic practices information, technical information, legal information and economic information. Similarly, Ballantyne (2009) opined that types of information needs (agricultural information inclusive) revolved around scientific/technical, commercial and legal information. Table 3 indicates that site selection, ploughing/tillage, adequate plant spacing and fertilizer application rate were the major agronomic practices information needs of the farmers with mean score of 3.0 were the most frequently sought. This is similar to the findings of Deribe (2020) who found that the most sought information by farmers was on crop production. Furthermore, the findings, Opara (2008) claimed that farmers all over the world require a range of information from the weather, loans, soil, seeds, farming mechanisms, control and management, harvesting, storage, marketing, sale, investments and repayment of loans. Storage techniques was ranked the most frequently needed technical information ($\bar{x}$ =2.99). Storage loss had always been a major bottleneck to agricultural development especially perishable crop like Tomato, so there is great need for technical information on storage to enhance income realizable from Tomato production. This corroborates Ugboma (2010) in a study on access to agricultural information by fish farmers in the Niger Delta region of Nigeria, where it reveals that 98 percent of fish farmers studied preferred scientific/technical information According to Demiryureket *al.* (2008) technical information is considered as a basis for material and intellectual sources in different societies and any society which is able to access more information automatically has more potentiality.

Furthermore, weather forecast/drought ($\bar{x}$ =2.59) was ranked the most frequently needed legal. Other legal information needs on Tomato production include environment use rules ($\bar{x}$ =2.37), food quality and safety ($\bar{x}$ = 2.10) and information on land use policies/rules ($\bar{x}$ =2.02). The findings therefore indicate that weather forecast/drought was ranked the most frequently needed legal information. This implies that farmers need this information in order to schedule their cropping season appropriately. Marketing of produce and farm management were ranked the frequently needed economic information ($\bar{x}$ =2.71) which include price control, price of fertilizers, price of seeds, and sale of agricultural products. Maru (2008) and Renwick (2010) in separate studies carried out in India and the Caribbean respectively reported that economic information that is related to production, productivity, profit enhancement, commodity price, food quality, safety and labeling information.

Table 3: Distribution of respondents by agricultural information needs on Tomato production (n = 189)

S/N	Information Needed	Mean	Rank
	Agronomic practices information		
1	Site selection	3.00	1st
2	Clearing operation	2.94	10th
3	Ploughing/tillage	3.00	1st

5	Marketing of produce	2.71	1st
	Mean		

Categorization of agricultural information needs of farmers on Tomato production

Based on the results in Table 4, about 9.5 percent of the respondents required agricultural information on Tomato production at high level, 60.9 percent of the respondents needed agricultural information on Tomato production at moderate level while 29.6 percent of the respondents need agricultural information on Tomato production at low level. The findings revealed that most of the respondents still fall within moderate level of agricultural information on Tomato production which therefore require intensive sensitization on importance of adequate information so as to boost Tomato production.

Table 4: Categorization of agricultural information needs of farmers on Tomato production

Categorization		Frequency	Percentage
High	$> \bar{x} \pm SD = 103.44$	18	9.5
Moderate	$\bar{x} \pm SD = 103.44$ to 89.06	115	60.9
Low	$< \bar{x} \pm SD = 89.06$	56	29.6
Total		189	100.0

Hypotheses for the study

Table 4 shows the summary of Regression analysis (Exponential function) of the relationship between respondent' personal characteristics of Tomato farmers and their information needs. It was revealed that age of the respondents (t = 5.60***), **y**ears spent in school (t = 8.91***) and output from Tomato production (t = 2.20**) were significantly related with respondents' information needs on Tomato production. The relationships were positive which implies that increase in the significant variables of the respondents will bring about an equivalent increase in the respondents' information needs on Tomato production. For instance, increase in the age of the farmers will afford them better understanding of Tomato production and marketing and this will increase their information needs on Tomato production which will invariably improve output of Tomato production. This is similar to the findings of Ogunleye et. al. (2012) who found that age influences training needed by farmers. Moreover, education brings about exposure and acquisition of improved knowledge especially Tomato production and this will help increase need for information on Tomato production which will translate to improved output from Tomato production and better income level for the farmers. Also, as the output from Tomato production is increasing, farmers will tend to seek more information on processing and marketing of Tomato production. Though size of farm is positive but not significantly related to information need in Tomato production. This finding is contrary to the report of Abu *et al*. (2011) found that the farm size is significant in impacting farmers' information need on Tomato production. The adjusted R-square for the relationship was found to be 0.9873 which implies that the independent variables had 98.7% influence on the dependent variable. The value vividly indicates that age, years of schooling and output from Tomato production are strong determinants of information needs of Tomato farmers in the study area. Since there is a significant relationship between the dependent and the independent variables for this study, the null hypothesis is therefore rejected while the alternative hypothesis is accepted. Therefore, there is significant relationship between personal characteristics of Tomato farmers and respondents' information needs on Tomato production.

Table 5: Summary of regression analysis of the relationship between personal characteristics and information needs on Tomato production

Personal characteristics	Coef.	Std. Err.	t-value	P>|t|	Decision
Age	0.0099426	0.001777	5.60***	0.001	S
Years spent in school	0.0339519	0.0038115	8.91***	0.001	S

R-squared = 0.9879, Adj R-squared = 0.9873, S = Significant, NS = Not Significant
**Significant at 5% level; ***Significant 1%

CONCLUSION AND RECOMMENDATIONS

On the basis of the major findings of this study, it was observed that age of the respondents, years spent in school and output from Tomato production were significantly related with respondents' information needs on Tomato production while the information seeking behaviour is motivated purposely to improve general knowledge, improve yield of crop, access reliable and timely information and to improve the quality of decision making. It was therefore concluded that respondents were in keen need of information on Tomato production.

Based on the findings and conclusion of the study, the following recommendations are necessary:

1. Since years of schooling is an important determinant of information seeking behavior, there is adequate need to expose Tomato farmers by extension agents to necessary information on Tomato production especially through diverse media in order to enhance their decision making profile as a result of their exposure to outside world.
2. Agricultural Extension organizations should provide training to farmers in the areas of agronomic practices, technical, legal and economic needs of Tomato production to cater for their information needs for improved overall performance of Tomato farmers.
3. Tomato farmers should be motivated by government in the area of price control and buy off of products when price is unfavourable so as to increase their level of production for national development.

ABSTRACT
Factors such as population growth, deforestation and poor farming techniques have been pointed out as the major causes of increased growth in human activities, overgrazing, deforestation, and the use of inappropriate farming practices. Consequently, this research aims to assess the adoption of land management technologies by crop farmers in Offa Local Government, Kwara State Nigeria. A quantitative analytical study was conducted using a Multistage Sampling Technique involving 120 farmers in Kwara state. The collected responses were analyzed using descriptive statistics. The analysis revealed intercropping (98.3%), crop rotation (99.2%), bush fallowing (99.2%), cover cropping (97.5%), whereas strip cropping (3.3%), terracing (9.2%), and contour ploughing (14.2%). This implies that there is high level of awareness of sustainable land management technologies in the study area. which will aid extension agents in making Farmers adopts this method. Extension agents should be made available to the crop farmers in other to help guide the farmers on the use of sustainable land management technologies.
Keyword: *Adoption, Sustainable Land, Management Technologies, Horticultural Extension, Kwara State.*

INTRODUCTION

One out of every three people on earth in some way or the other affected by land degradation per average, latest estimates indicates that nearly 2 billion hectares of land worldwide are already degraded, some irreversibly (FAO, 2010). Factors such as population growth, deforestation and poor farming techniques have been pointed out as the major causes. Human growth has resulted in increased human activities and land demand, which triggered overgrazing, deforestation and use of inappropriate farming practices (Semgalawe, 1998; Senkodo, 2009). To rescue this situation, the adoption of sustainable land management practices seems to be the best way. Estimate put 300,000 to 400,000 hectares of forest that are cleared every year to meet the demand for farming land, timber, poles and firewood (Semgalawe, 1998; Senkondo, 2009).

Sustainable land management has been defined as the adoption of appropriate land management practices that enables land users to maximize the economic and social benefits from the land while maintaining or enhancing the ecological support functions of the land resources (FAO, 2009). It is the key point for improving land resources resilience and productivity within the context of the potentially devastating effects of climate change in sub-Saharan Africa, bringing the needs of agriculture and environment, with the twin objectives of maintaining long term productivity (quality, quantity and diversity) of goods and services. The major goal of sustainable land management therefore is to develop economically viable agro-ecological system and to enhance the quality of the environment.

The practices include Diversified cropping systems (strip cropping, and mixed intercropping). Integrated agro-forestry practices with the cropping system and soil erosion control structures and practices that is contour farming and grass barriers (Roberts *et al* 2008). These practices are a key mechanism for effecting change in the sustainable use and management of land resources (Webb, 2004). Unsustainable land management practices can threaten biodiversity and increase the release of Carbon especially through destruction of forests as well as impacting adversely on water resource management. On the other hand, they present opportunities for enhancing the livelihoods of the poor and fostering inclusive growth as well as for achieving environmental goals (UNCCD and FAO, 2009).

RESEARCH PROBLEM

Soil erosion remains the most common environmental degradation or ecological problem in Nigeria. This phenomenon which results from the impact of climatic factors, particularly rainfall, and wind is exacerbated by uncertainties arising from climate change effect that occurs both where it directly affects crops or plants where they are growing, and off-site with environmental consequences that manifest as pollution of natural water, impairment of air quality by dust or emission of radio-active gases. Other effects include damage to infrastructure, citation of water ways and reservoirs as well as, increased cost of water treatment.

It has also been observed that information about sustainable and relevant sustainable land management technologies is not readily available to farmers in Nigeria generally, making informed choice about the best possible sustainable land management technologies to be adopted for best result has become difficult due to the fact that most farmers are not informed, government policy do not favor some sustainable land management technologies while some sustainable land management technologies are too expensive to be adopted. It is estimated that millions of metric tonnes of soil are lost to water and wind erosion annually (Souleman et al, 1993). Available statistics in Nigeria shows that over 300gullies existed in Abia state, 270 in Anambra state, 200 in Enugu state, and 250 in Imo state (Ugoriji, 1995). In the light of the above, the question that readily comes to mind is what has been happening to the researches on land management in the study area. Therefore, it is important for the crop farmers in the area to know about the different sustainable land management technologies that can combat this erosion problem and adopt these technologies. It is also pertinent to know the socio-economic and limiting factors associated with the adoption of sustainable land management technologies in the study area

RESEARCH OBJECTIVES

The general objective of this study is to assess the adoption of land management technologies by crop farmers in the study area.

The specific objectives of this study include:

1. ascertaining the level of adoption of the land management technologies
2. determining the constraints militating against the adoption of sustainable land management technologies by the respondents in the study area.

HYPOTHESIS

There is no significant relationship between the level adoption of sustainable land management technologies and the constraints militating against its adoption

JUSTIFICATION OF THE STUDY

It has been observed that there are no studies done on assessing the impact of adoption of sustainable land management strategies in the community. If crop farmers know the impacts of practicing sustainable land management (SLM), it will enable the sustainability of land management practices in Offa local government. In addition, this study will build the strong base to farmers whether offered sustainable land management technologies are worthwhile undertaking or not. Furthermore, study findings will contribute in policy reforms especially on the land conservation.

METHODOLOGY

Study area

The study was carried out in Offa Local Government, Kwara State, Located in central Nigeria with latitude 8.15° North and longitude 4.72° East and 436 meters elevation above the sea level and with population of about 113,830 inhabitants. The population of the study comprised of all crop farmers in Offa local government area.

Sampling procedure

There are 12 wards in Offa local government, thus multistage random sampling technique was used for data collection. First, 5 wards were randomly selected from the 12 wards in the local government area and then a total of 24 crop farmers were randomly selected from the list of crop farmers from each of the 5 randomly selected wards making a total of 120 crop farmers which were interviewed.

Data collection method

Both primary and secondary data were collected for this study. Primary data was collected through the administration of a well structured interview schedule to the selected crop farmers. Information included in the instrument was guided by the objectives of the study. While secondary data was obtained from proceeding reports, textbooks, journals and the internet.

Data analysis

The data for this study was analyzed using both descriptive and inferential statistics. The descriptive statistics used for this study included frequency counts, percentages and mean. Chi-square was the inferential statistics used to test the hypothesis.

RESULTS AND DISCUSSIONS

Table 1: Distribution of respondents according to their level of adoption of sustainable land management technologies, n=120

Sustainable land management technologies	Frequency (%) Always	Frequency (%) Often	Frequency (%) Occasionally	Frequency (%) Not at all	Weighted mean score	Rank
Intercropping	100 (83.3)	5 (4.2)	15 (12.5)	_____	2.71	1st
Crop rotation	78 (65.1)	34 (28.3)	7 (5.8)	1 (0.8)	2.58	2nd
Bush fallowing	13 (10.8)	74 (61.7)	32 (26.7)	1 (0.8)	1.83	3rd
Cover cropping	18 (15.1)	56 (46.7)	41 (34.2)	5 (4.2)	1.72	4th
Use of fertilizer	2 (1.7)	15 (12.5)	62 (51.7)	41 (34.1)	0.82	5th
Mixed farming	3 (2.5)	8 (6.7)	43 (35.8)	66 (55.0)	0.57	6th
Mulching	3 (2.5)	2 (1.7)	28 (23.3)	87 (72.5)	0.34	7th
Strip cropping	_____	1 (0.8)	2 (1.7)	117 (97.5)	0.03	8th
Contour ploughing	_____	1 (0.8)	2 (1.7)	117 (97.5)	0.03	8th
Terracing	_____	_____	2 (1.7)	118 (98.3)	0.02	10th

Table 2: Distribution of the respondents according to the constraints militating against the adoption of sustainable land management technologies, n=120

Constraints	Frequency (%) Very severe	Frequency (%) Severe	Frequency (%) Mild	Frequency (%) No a constraint	WMS	Rank
High cost of production	105 (87.5)	12 (10)	2 (1.7)	1 (0.8)	2.84	1st
Insufficient extension service	30 (25%)	75 (62.5)	5 (4.2)	10 (8.3)	2.57	2nd
High labor cost	85 (70.8)	32 (26.7)	2 (1.7)	1 (0.8)	2.67	3rd
Unavailability of credit	31 (25.8)	73 (60.8)	14 (11.8)	2 (1.6)	2.12	4th
Unavailability of labor	_____	9 (7.5)	61 (50.8)	50 (41.7)	0.66	5th
Inadequate knowledge of modern technique	_____	1 (0.8)	42 (35.0)	77 (64.2)	0.37	6th
Low produce price	_____	2 (1.7)	32 (26.7)	86 (71.6)	0.30	7th
Insufficient land availability	_____	4 (3.3)	7 (5.9)	109 (90.8)	0.13	8th
Transportation problems	_____	_____	11 (9.2)	109 (90.8)	0.09	9th

CONCLUSION

The study concludes that high cost of production, insufficient extension service, high labor costs and unavailability of credit facilities were the major problems affecting the adoption of sustainable land management technologies.

By using chi-square the study found that we have enough evidence to reject the null hypothesis that states that; there is no significant relationship between the level adoption of sustainable land management technologies and the constraints militating against its adoption because majority of the constraints have significant relationship with the level of adoption of sustainable land management technologies.

RECOMMENDATIONS

Sustainable land management practices are of great important for their significant positive impacts to our daily life. This has been observed from economic analysis and findings of this study.

First, the crop farmers should form financial organizations among themselves to help them generate money in other to solve their problem of high cost of production, high labour cost and unavailability of credit.

Second, crop farmers should develop low income methods of land management; this will act as a backup mechanism for those low income farmers to adopt land management technologies.

Finally, extension agents should be made available to the crop farmers in other to help guide the farmers on the use of sustainable land management technologies.

ABSTRACT
Shockingly, an estimated 53,000 women lose their lives annually, equating to one woman succumbing to maternal-related issues every ten minutes. This alarming statistic translates to approximately 800 women losing their lives for every 100,000 live births. This study therefore aims to investigate the media advocacy of maternal health news in the print media. A quantitative analytical study of 370 articles of the three newspapers were collected. The collected responses were analysed using descriptive statistics. The analysis revealed that news on maternal mortality had the highest percentage of 49.5%, followed by 20.5% news on pregnancy-induces high blood pressure in the selected newspapers. The least dominant news types were news on malaria (0.5%) and lack of quality health care formal providers (1.1). News reporters (28.4%) dominated sources of information often quoted. Other sources quoted were (research Institutes which had 1.6%, government official 19.5%, NGOs 13.0%, university scientist 4.9%, health personnel 9.5%, residents and victims 2.4%, international organisations 10.0%, in the three selected newspapers. This implies that there is high level of awareness of maternal health condition. These conditions could be addressed through simple ways like creating awareness and improving education on the problems causing it.
Keyword: *Media Advocacy, Gendered analysis, Maternal health, Newspaper coverage, Nigeria*

INTRODUCTION

Maternal ill-health occurs as a result of complications of pregnancy and childbirth. About 53,000 women die every year, which means one woman dying every ten minutes. This means about 800 women die in every 100,000 live births. Many people do not readily appreciate this disaster because the deaths do not occur together or in one place. They occur silently in the many different communities in Nigeria. (Maternal Health Fact Sheet, 2007). They die from complications during pregnancy and delivery, which include: excessive bleeding (or haemorrhage), infections, pregnancy-induced high blood pressure leading to convulsions, unsafe abortion, anaemia, malaria, and obstructed labour. The World Health Organization (WHO) estimates that over 500,000 women and girls die from complications of pregnancy and childbirth each year, worldwide, with approximately 99% of these deaths occurring in developing countries. According to Ogunjuyigbe and Liasu, A. (n.d.); and WHO (2007) for every woman that dies from pregnancy-related causes, 20 – 30 more will develop short- and long-term damage to their reproductive organs resulting in disabilities such as obstetric fistula, pelvic inflammatory disease, a ruptured uterus.

Maternal health is very important because childbearing is a key part of women's lives which occurs mainly in the adolescent and adult years. This is also their most productive time when women strive to fulfil their potential as individuals, mothers and family members, and also as citizens of a wider community. Poor maternal health can have significant negative impact on the family and society as it is a major determinant of the health of children and can also have huge costs on families in emotional, health and economic terms. Direct medical costs, loss of income and other economic contributions, potentially put the family in economic distress. The risk of a woman dying as a result of pregnancy or childbirth during her lifetime is about one in six in the poorest parts of the world compared with about one in 30,000 in Northern Europe. Such a discrepancy poses a huge challenge to meeting development goals set form time to time.

The need for media involvement in promotion of healthcare is pertinent considering the poor state of the Nigerian health sector, with the country ranking below global and African regional average across various health indices (World Health Organisation, 2014). Maternal and child healthcare (MCH) is an important developmental issue affecting every constituency in Nigeria, though with wide disparities across the geographical regions and social strata (National Population Commission & IFC International, 2014). Media serve as health reformer that has the power of bringing buried topics to the spotlight. By highlighting these ignored issues and neglected segments, media helps to bring public health to the policy agenda. Newspapers are enduring and very popular print media organ. This is because it can be read and re-read at convenience, thus, allowing for a fuller and better understanding of mass media contents. Newspapers also help the process of information exchange between those searching for information and also support new behaviours (Albrecht *et al*, 1989; Lightfoot, 2003). In essence, the newspapers are potent and fundamental tools for technology transfer in the aid of agricultural and rural development and associated issues that affect the rural populace such as maternal health.

In spite of increasing in maternal death, it appears Nigeria's media; especially the newspapers are not doing enough to bring this to limelight. This is probably due to competing demand for much news worthy issues and even paid advertorial to fulfil the commercial purpose of the prints media. It is in light of the aforesaid that this study investigated the pattern of reporting coverage of rural maternal health news in the Nigerian newspapers to empirically validate series of concerns emanating from this trend and consequently chart ways to improving the current level of reportage of maternal health news in Nigerian newspapers. In doing this the study investigated specifically types of maternal health news covered and the sources quoted in the Nigeria newspapers.

MATERIALS AND METHODS

Three out of ten widely read newspapers were randomly selected for the purpose of data collection and analysis for this study. Pre-test showed that the three selected daily newspapers report maternal health news routinely. Also, they were most widely read thereby having a wider coverage in Nigeria as noted by Nigeria Press Council (2010). All newspaper editions reporting maternal health news in the Punch, the Guardian and the Nigerian Tribune newspapers constituted the population for this study. Articles that were selected for the research include; news articles, feature article and culled articles. The unit of analysis for this study was individual article reporting maternal health news in the selected newspapers. Descriptive statistics (frequencies and percentages) were used to arrange and describe the data collected while inferential statistics such as chi-square (x^2) were used to test for relationship and (ANOVA) were used to test for differences between study variables.

RESULTS AND DISCUSSION

From the analysis of the reviewed maternal health news reported in the Punch, Guardian and the Nigerian Tribune newspapers, eight frames emerged: education, awareness, government intervention, advertisement, innovation, blame, punishment and criticism. Results in Table 1 show the type of news that was reported by the newspapers within the study's time frame. This result shows that the types of news that were reported as a result of maternal health was maternal mortality (49.5%) and on pregnancy-induces high blood pressure (20.5%). Out of the various news types that are reported, news about maternal mortality had the highest percentage in the three newspapers which had 49.5% and this was followed by pregnancy-induces high blood pressure news had 20.5%. Infection had 14.6% news, lack of awareness had 5.7%, unsafe abortion had 5.4%, Haemorrhage had 1.4%, inaccessible/transportation had 1.4%. News type with the lowest percentage is news that reports on malaria and lack of quality health care formal providers. Malaria had 0.3% in Punch, 0% in Guardian and 0.3% in the Nigerian Tribune. The Guardian newspaper did not report news on malaria. The Nigerian Tribune newspaper as well did not give any report on news pertaining to lack of quality health care formal providers.

News about maternal mortality which had the highest percentage (49.5%) in the three newspaper comprises of maternal death/morbidity, Female Genital Mutilation (FMG), child labour/child abuse, sexually transmitted diseases and HIV, unsafe abortions/unwanted pregnancies, Forced and early marriage, under nutrition of the girl child are conditions that could lead to maternal death. These conditions could be addressed through simple ways like creating awareness and improving education on the problems causing it.

Table 1: Showing the news types that were reported by the three newspapers.

News type	Newspapers			Total
	Punch	Guardian	Tribune	
Malaria	1 (0.3)	0 (-)	1 (0.3)	2 (0.5)
Infections	10 (2.7)	27 (7.3)	17 (4.6)	54 (14.6)
Unsafe abortion	8 (2.2)	9 (2.4)	3 (0.8)	20 (5.4)
Maternal Mortality	57 (15.4)	71 (19.2)	55 (14.9)	183 (49.5)
Lack of awareness	10 (2.7)	8 (2.2)	3 (0.8)	21 (5.7)
Haemorrhaged	3 (0.8)	2 (0.5)	3 (0.8)	5 (1.4)
Lack of quality healthcare formal providers	2 (0.5)	2 (0.5)	0 (-)	4 (1.1)
Pregnancy- induced high blood pressure	39 (10.5)	14 (3.8)	23 (6.2)	76 (20.5)
Inaccessible and transportation system	1 (0.3)	1 (0.3)	3(0.8)	4 (0.3)
Total	131 (35.4)	134 (36.2)	105 (28.4)	370 (100)

The sources quoted in the reported maternal health news:

The results in Table 2 indicate sources used in reporting maternal health news by the newspapers included in this study. This result shows that the newspaper obtained information from two (2) major sources which are news reporters having a total of 28.4% and government official having a total of 19.5%. Government official group comprised of any position within the government that was hired or appointed while, the news reporter reporting an event or loss of live/ maternal death that is caused by maternal health challenges and factors. The highest sources of information that were mostly quoted are the news reporters which had 28.4%, and this was followed by Government official (19.5%) in the selected newspapers. Sources from research Institutes and residents and victims are sources of information with the lowest percentage 0.3% and 1.1% respectively. The Punch newspaper had the highest percentage (11.1%) sources of information from the news reporters. while The Nigerian Tribune had the highest percentage (7.3%) sources of information from Government official. The Nigerian Tribune had the lowest percentage source of information from the research institute (0.3%) and university scientist (1.1%) respectively. This result shows that major source of information used by the three newspapers is news reporters and Government officials which is not a reliable source because the public always prefer information from reliable sources such as experts and university scientist.

Table 2: Sources for maternal health news in the newspapers

News Sources	Newspapers			Total
	Punch	Guardian	Tribune	
Government Official	22 (5.9)	23 (6.2)	27 (7.3)	72 (19.5)
NGOs	9 (2.4)	26 (7.0)	13 (3.5)	48 (13.0)
University Scientists	6 (1.6)	8 (2.2)	4 (1.1)	18 (4.9)
Research Institutes	4 (1.1)	1 (0.3)	1 (0.3)	6 (1.6)
News Reporters	41 (11.1)	39 (10.5)	25 (6.8)	105 (28.4)
Health Personnel	18 (4.9)	7 (1.9)	10 (2.7)	35 (9.5)
Residents and Victims	3 (0.8)	4 (1.1)	2 (0.5)	9 (2.4)
International Organizations	9 (2.4)	16 (4.3)	12 (3.2)	37 (10.0)
Researchers	19 (5.1)	10 (2.7)	1 1 (3.0)	40 (10.8)
Total	131 (35.4)	134 (36.2)	105 (28.4)	370 (100)

CONCLUSION

The study concludes as follows:

- Maternal mortality was the highest news type that was mainly reported.
- The major source of information reported on maternal health news are the news reporters and government officials.

RECOMMENDATIONS

Based on the findings of the study, the following recommendations are made:

- The Nigerian newspaper industry should give more prominence to maternal health news and also increase their frequency of reportage in the selected newspapers.
- Other frames of malaria, lack of quality healthcare formal providers, and inaccessible and transportation system should also be accorded due coverage.
- The media should provide an open forum to reflect different public views, including those of economically poor people, to create awareness to the public more about the importance of maternal health coverage.

ABSTRACT
Coffee (C.arabica and C.robusta) in Nigeria has declined production due to climate change. Data of 1961-2021 from FAOSTAT consisting area(ha), yield (kg/ha) and annual temperature(^{0}C) was analysed using least squares regression. Results showed 861.8kg/ha average yield from 4201.4ha mean area in 61 years. The temperature/annum decreased by 0.0007^{0}C for 11 years and increased by 0.0200^{0}C for 50 years at 0.6380 and 0.0014 R^2 respectively. The coffee yield/annum for 11 years temperature decrease by 63.6%, 27.3% and 9.1% in the 60s, 70s and 80s and for 50 years increase by 4%, 14%, 18%, 20% and 44% in the 60s, 70s, 80s, 90s and 2000s was 14.2kg/ha and 20.9kg/ha respectively. The correlation was inverse (-0.318) between yield and temperature decrease and direct (0.713) with temperature increase. The coffee yield and temperature was inverse (-0.058, -0.649) respectively in the 60s and 80s. To enhance coffee yield, temperature threshold should be maintained through good agricultural practices in the plantations.
Keywords: *Temperature variations, Coffee yield, Nigeria, climate change, FAOSTAT*

INTRODUCTION

Coffee (*Coffee arabica and Robusta coffee*) is a perennial woody tree crop. It is a shade-loving tree that well-known for helping to preserve the ecology **(**Akinpelu *et al.,* 2021**)**. The coffee berry or cherries contain the seeds, often known as coffee beans. The coffee plant is indigenous to Africa, with its origin linked to Ethiopia, Central Africa, and West Africa **(**Ayoola *et al*., 2012**;** ICC, 2015**)**. Coffee grows between the latitudes of 25°N and 25°S, but commercial growing requires peculiar environmental conditions **(**Ogundeji *et al*., 2019**)**. Nigeria has a land area of around 923,769 km^2, although only about half of it is currently cultivated (Onwusiribe *et al.,* 2022). In 2019, the land area utilised for coffee growing was expected to be 10 km^2, whereas in 1981, the land area used for coffee farming was 60 km^2. Agriculture in Nigeria is mainly influenced by the weather, with possible irrigation areas ranging from 1.5 to 3.2 million hectares. The coffee-producing states in Nigeria include Bauchi, Kwara, Plateau, Taraba, Cross River, and Osun; however, there are also temperate zones in Nigeria that can support coffee production. Nigeria's low coffee output is due to a combination of factors, including poor farming practices, low mechanisation, limited access to funding and inputs, and the effects of the climate **(**PwC, 2017**;** Mohammed *et al.,* 2013**;** Ayoola *et al.,* 2012**)**. Temperature, rainfall, sunlight, wind, and soils are crucial in coffee production, but the needs vary depending on the cultivated varieties **(**Ayoola *et al*., 2012**)**.

The changing climate in the tropics, particularly in terms of altered rainfall patterns and extended dry spells in most parts of Nigeria, has led to soil water balance changes, flooding, drying up of water bodies, and desert encroachment. Due to delayed rainfall in some of the producing regions, coffee production in Nigeria was expected to decline in the 2020/21 farming season **(**Bjornlund *et al*., 2020**;** Malhi *et al.,* 2021). In addition, the increase in the incidence of pests and diseases that harm the coffee tree, such as parasitic nematode, coffee berry borer, leaf rust, coffee berry disease, brown eyespot, and coffee wilt disease, is linked to climate variations **(**Gizaw *et al.,* 2021**;** Ogundeji *et al.,* 2019**)**. The majority of small-scale coffee producers are abandoning their farms due to climate change and production issues outside the farmers' control. These conditions impact the productivity of most small-scale coffee farmers, lowering their income. Longer drought spells and interrupted flowering cycles are two examples of climate change impacts on coffee, resulting in decreased quantity and quality of coffee harvested **(**Gizaw *et al.,* 2021**;** Ogundeji *et al.,* 2019**)**. Coffee will go extinct unless suitable climate change mitigation and adaptation methods are implemented, which include conservation, monitoring, and seed preservation **(**Ogundeji *et al.,* 2019**;** Duke & Cornell, 2019**)**.

According to Kollipara (2014)**,** the issue of global warming and other climate change effects must be treated as an emergency, or the land area suitable for coffee farming will decline by 50%, affecting global coffee output. Given the importance of coffee worldwide, the output decline in Nigeria in past decades occasioned by low prices on the international market, limited access to production factors, and the effects of climate change posed the most significant challenge. For example, in 1966, Nigeria produced 4000 tonnes of coffee, but in 1967, it only produced 1712 tonnes due to political unrest that hindered access to production assets. In 1969, Nigeria produced 4776 tonnes of coffee, whereas, in 1979, Nigeria produced 3200 tonnes. Recently in 2019, the output of coffee was 1117, which declined from 2400 tonnes recorded in 2010 **(**FAO, 2021**).** Land, capital, output and input prices, and climatic factors are all important factors influencing the short run and long run coffee production **(**Nchare, 2007**).** These factors make small-scale coffee farmers more vulnerable to postharvest losses of more than 50% **(**Kasso & Bekele, 2018**;** Baca *et al.,* 2014**).** The research is aimed at proposing climate change mitigation strategies to enhance optimum coffee yield.

MATERIALS AND METHODS

Data on area harvested (ha), yield (kg/ha) and temperature (^{O}C) in Nigeria was sourced from the database of Food and Agricultural Organisation Corporate Statistical Database (FAOSTAT); the duration was 61 years (1961 - 2021). The data were analysed using least squares regression.
The least squares line method uses a straight line
$Y = a + bx$
to approximate the given set of data, $(x_1,y_1), (x_2,y_2), \dots, (x_n,y_n)$, where $n \geq 2$
Where 'a' stands for the intercept and 'b' stands for the slope; x and y are the variables. The slope is equivalent to variation in coffee yield and temperatures per year (Kadioglu, 1997). To measure the association between the variables, correlation analysis was done.

RESULTS AND DISCUSSION

Temperature variations and coffee yield statistics

Table 1 states the inter annual coffee yield statistics from the 60s to 2000s while Table 2 shows the cumulative yield statistics during the periods of temperature variations.

Table 1: Coffee inter annual Yield Statistics

Variables	Inter Annual Yield Statistics									
	60s		70s		80s		90s		2000s	
	Yield (kg/ha)	Temp (^{0}C)	Yield (kg/ha)	Temp (^{0}C)	Yield (kg/ha)	Temp (^{0}C)	Yield (kg/ha)	Temp (^{0}C)	Yield (kg/ha)	Temp (^{0}C)
Minimum	183.3	0.0136	499.5	0.0928	500.0	0.2923	882.4	0.0004	1133.3	0.4378
Maximum	666.7	0.4743	500.2	0.8040	523.3	1.0181	1198.1	1.1465	1439.4	1.4368
Mean	408.8	0.1776	500.0	0.2958	502.6	0.5217	1005.2	0.6570	1284.1	1.0319
Standard deviation	160.8	0.1596	2.1492	0.2663	77.7	0.2214	1007.8	0.3183	699.2	0.2821
Correlation Analysis	-0.649		0.143		-0.058		0.502		0.073	

Table 2: Coffee cumulative yield statistics

Variables	Cumulative Yield Statistics			
	Yield Statistics at temperature decrease (60s – 80s)		Yield Statistics at temperature increase (70s – 2000s)	
Minimum	183.3	0.0136	333.3	0.0004
Maximum	755.9	0.4743	1439.4	1.4368
Mean	465.3	0.1710	949.1	0.7333
Standard deviation	163.0	0.1380	358.7	0.3918
Correlation Analysis	-0.318		0.713	

As shown on Table 1, throughout the 61 years of observation, coffee yield was minimum (183.3kg/ha) in the 60s at mean surface temperature of 0.1776 ^{0}C and standard deviation of 160.8kg/ha while in the 2000s, the yield was maximum (1439.4kg/ha) at a mean surface temperature of 1.0319^{0}C and standard deviation of 699.2 kg/ha. There is an inverse correlation between coffee yield and temperature in the 60s (-0.649) and 80s (-0.058) while in the 70s, 90s and 2000s, the correlation was positive (0.143, 0.502 and 0.073 respectively). Considering the coffee cumulative yield statistics (Table 2) throughout the individual years of temperature decrease (60s – 80s) as well years of increase (70s – 2000s), it can be observed that yield was minimum (183.3kg/ha) at a mean temperature of 0.1710^{0}C and standard deviation of 163.0kg/ha in the individual years of 60s to 80s while the maximum yield (1439.4kg/ha) at mean temperature of 0.7333^{0}C and standard deviation of 358.7 kg/ha was observed in the individual years of 70s to 2000s. There is an inverse correlation (-0.318) between temperature and coffee yield during the periods of temperature decrease and positive correlation (0.713) between both variables during the years of temperature increase.

Regression analysis of coffee yield Trend

Figures 1 and 2 shows the trend in coffee yield during the 11 years of temperature decrease and 50 years of increase respectively.

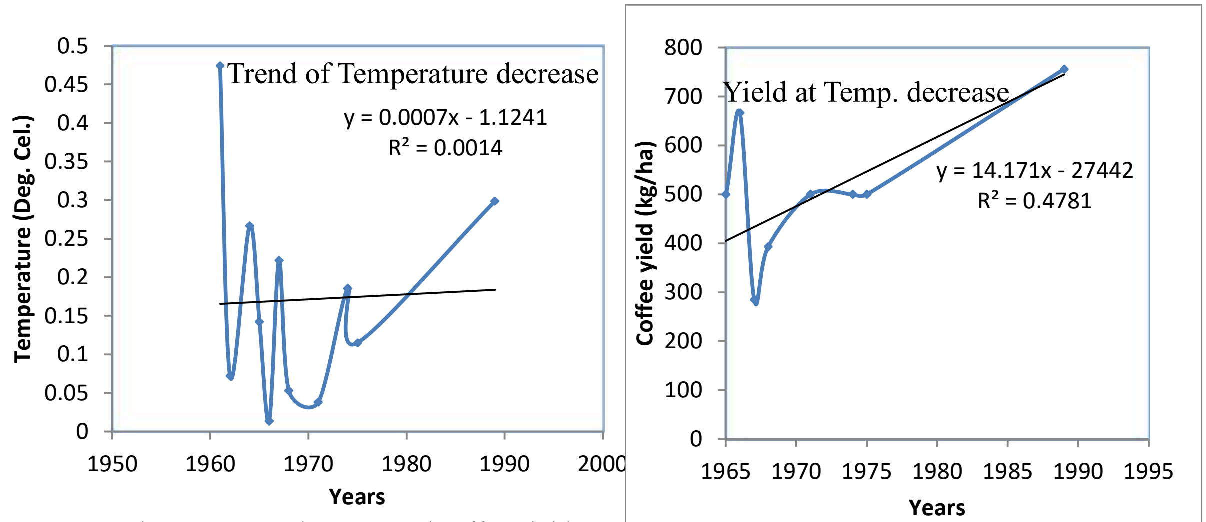

Figure 1: Annual temperature decrease and coffee yield

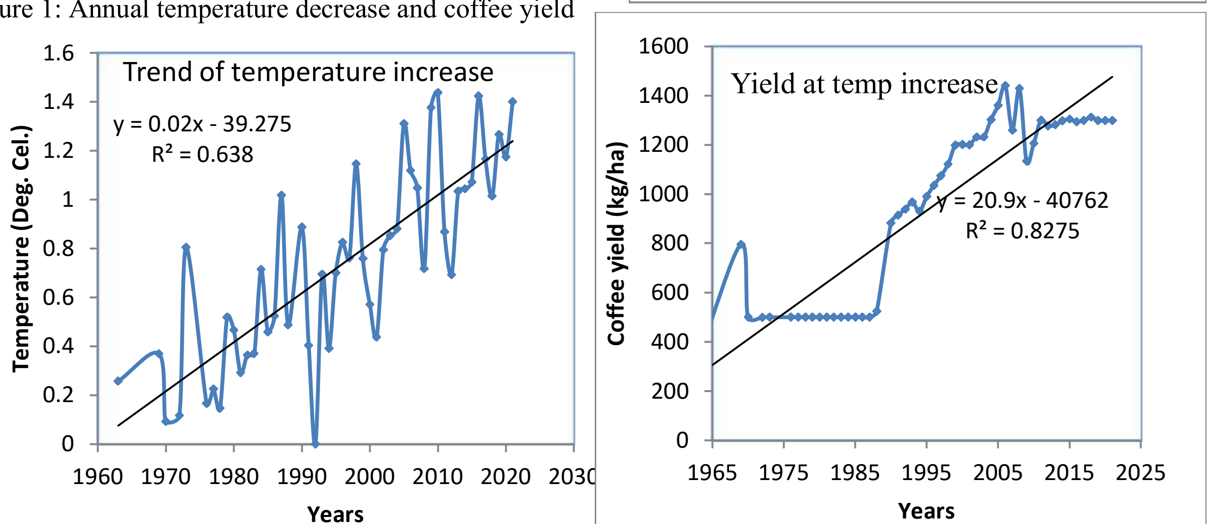

Figure 2: Annual temperature increase and coffee yield

The results presented in Figures 1 and 2 revealed an annual temperature of increase 0.0200^{o}C at R^2 value of 0.6380 and 0.0007^{o}C decrease at the R^2 of 0.0014. There was increase of coffee yield of 20.9kg/ha per annum during the 50 years of temperature increase while the yield decreased by 14.2kg/ha in 11 years of temperature decrease. The R^2 values were 0.8275 and 0.4781 respectively.

CONCLUSION

Nigeria has a land area of around 923,769 km^2 but only about 60 km^2 is utilised for coffee cultivation and yield has been affected by climate change. The result obtained revealed 82% of temperature increase in 50 years and 18% decrease in 11 years at R^2 value of 0.6380 and 0.0014 respectively. During the period of temperature increase, the coffee yield increased by 20.9kg/ha per annum at R^2 values were 0.8275 while the yield decreased by 14.2kg/ha at R^2 value of 0.4781 when there was temperature decrease. The decrease in yield can be mitigated by the use of standard cultural practices and other standardisation practices by coffee farmers inorder to produce efficiently and meet the demands of the international coffee market.
